Routine radiographs are useful to rule out old or chronic fractures (most commonly of the fibula, tibia, talus, and fifth metatarsal), to assess the integrity of the ankle mortise, and to assess for ankle arthritis. A routine radiographic series should include anteroposterior, lateral, and mortise views. Widening of the ankle mortise may indicate a syndesmotic disruption or significant deltoid ligament tear. Radiographs should be obtained in all cases with a history of significant trauma at initial injury.

Stress radiographs may be helpful in determining the presence of chronic mechanical instability. Although the routine use of stress radiographs remains controversial, a finding of more than 5 mm of anterior displacement of the talus during anterior drawer testing is considered to be abnormal [8]. Inversion stress radiographs are considered abnormal with a finding of more than 5 degrees of side-to-side difference in tibiotalar tilt [7]. However, a review found the published data regarding stress radiographs too variable to determine accepted normal values for acute and chronic sprains [9]. The sensitivity of stress radiographs in diagnosis of chronic lateral ligament tears (surgically confirmed) is low, although specificity is high [8].

Computed tomography can identify subtle talus fractures and other bone disease, such as tumors. Bone scans are particularly helpful in identifying stress fractures and can be a useful screening tool to evaluate for ongoing ankle disease, such as significant arthritis, infection, tumors, and reflex sympathetic dystrophy. Magnetic resonance imaging and magnetic resonance arthrography generally give the most information about soft tissue injury, although they also

can be helpful in identifying fractures (such as osteochondral fractures), tumors, and chronic infections. Magnetic resonance imaging and magnetic resonance arthrography both have high specificity for identification of chronic ligament tears, but magnetic resonance arthrography has higher sensitivity [10]. The appropriate timing of advanced imaging is variable and governed by the clinical suspicion of further injury or pathologic change not evident on routine radiographs or persistent symptoms despite appropriate treatment. Figures 85.1 and 85.2 demonstrate anterior talofibular and calcaneofibular ligament tears as observed with ankle arthrography.

FIGURE 85.1 Ankle arthrogram. Anteroposterior view after ankle injection demonstrates extravasation laterally (arrow) resulting from anterior talofibular ligament tear. There is no filling of the peroneal tendon sheath. (From Berquist TH. *Radiology of the Foot and Ankle*, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2000. © Mayo Foundation, 2000.)

FIGURE 85.2 Ankle arthrogram. Anteroposterior view taken during ankle injection demonstrates filling of the peroneal tendon sheaths (arrow) resulting from calcaneofibular ligament disruption. (From Berquist TH. *Radiology of the Foot and Ankle*, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2000. © Mayo Foundation, 2000.)

Differential Diagnosis

Peroneal tendinopathy: subluxation, tear, chronic tendinitis
 Ankle impingement syndrome
 Sinus tarsi syndrome
 Subtalar instability
 Sprain: midfoot, subtalar
 Fracture: distal tibia-fibula, talar, osteochondral, stress fracture, fifth metatarsal, physeal
 Arthropathy: degenerative, inflammatory, crystalline, infectious

Treatment

Initial

The initial treatment regimen depends, in part, on symptom acuity and whether a recent sprain has occurred. Initial treatment options include ice massage, compression, elevation, taping or bracing, and nonsteroidal anti-inflammatory drugs or analgesics. The goal with bracing at this juncture is to prevent recurrent sprains and further tissue trauma. Comprehensive literature reviews indeed validate the use of ankle supports to prevent reinjury [11–13]. Many patients can successfully be weaned from external supports after rehabilitation. However, high-demand athletes may choose to brace or to tape during athletic participation indefinitely. A thin lateral heel wedge will put the ankle in slight valgus alignment and potentially diminish symptoms of instability and the tendency for spontaneous ankle inversion with activity. This can be considered in patients with normal alignment for short-term symptom management. Eventually, restoration of neutral foot and ankle alignment should be pursued through orthotic prescription. A three-quarter-length rigid medial longitudinal arch support is recommended in patients with pes planus. In patients with varus or valgus alignment of the ankle, wearing of a shoe that has a firm heel counter is recommended.

Rehabilitation

Rehabilitation starts by normalizing ankle range of motion, with primary emphasis on restoring ankle dorsiflexion and eversion. This typically includes Achilles tendon stretching with the knee straight (to stretch the gastrocnemius) and flexed 30 degrees (to stretch the soleus) as well as eversion (posterior tibialis) stretching. Care must be taken to avoid recurrent inversion stress to the ankle, which can perpetuate lateral capsuloligamentous laxity.

As symptoms allow, the patient begins an ankle muscle group strengthening program with an emphasis on ankle eversion strengthening. Resistance exercises can begin when there is no pain through the available range of motion, with full weight bearing [14]. The rehabilitation program may start with low-level strengthening, such as submaximal static exercises, and progress in a pain-free fashion to dynamic and isokinetic strengthening. Typically, a combination of open and closed kinetic chain strengthening is employed in the rehabilitation process [15]. Open kinetic chain exercises include the use of ankle weights and resistance tubing. Closed kinetic chain exercises are more functionally based; the foot is planted on the ground, and the patient engages in an activity that requires the activation of antagonistic muscles

that stabilize the ankle. Because eccentric muscle contractions place the greatest strain on the muscle, this mode of strengthening should be reserved for the final stages of the rehabilitation program.

Balance challenge and proprioceptive exercises are an important part of chronic ankle instability rehabilitation and have been found to decrease symptoms of functional instability as well as to reduce the rate of reinjury [16–18]. Ankle disks or wobble boards are devices that facilitate proprioceptive training. These exercises can be started without specialized equipment by having the patient perform a single-leg stance on the affected ankle; the skill level is then increased by having the patient close the eyes or stand on a pillow.

Functional exercises and sport-specific drills can begin when the patient has full range of motion, no pain, and at least 85% peroneal strength compared with the contralateral ankle [19]. These exercises add progressively difficult challenges and facilitate the attainment of dynamic strength and balance. Examples of these exercises are jogging, running, double-leg jumping, single-leg hopping, skipping rope, figure-eight drills, lateral cutting drills, and plyometrics. Patients should start at a low level of intensity and progress with increased intensity and difficulty only if they remain pain free while performing the exercise and have no pain or swelling after the training session.

Adjunctive modalities may be helpful throughout the rehabilitation process. These may include regular ice application (ice massage, ice pack, ankle Cryo/Cuff) after therapy sessions or heat application (superficial heat or ultrasound) to facilitate range of motion of a stiff joint. Electrical stimulation may be helpful for pain and edema control.

Procedures

Corticosteroid injections around the ankle ligaments are not advised and may further weaken the ligaments, accelerating mechanical instability. Prolotherapy, the injection of an irritant solution around the capsuloligamentous structures of the ankle, can be considered. The injectate (typically a low-concentration dextrose solution or a combination of phenol, glycerin, and glucose) acts as a local tissue irritant and activates the inflammatory cascade [20]. Given its mechanism of action, it can sometimes be a painful treatment. The purported result of this treatment is ligament and capsular hypertrophy causing reduction in laxity and thereby decreased pain [20]. At this time, no randomized controlled or large case series exists for the use of prolotherapy as a treatment of chronic ankle instability, but there is some suggestion of benefit in the treatment of knee laxity and pain due to osteoarthritis [21,22]. Further research is required.

Surgery

Surgery should be considered for patients who sustain recurrent lateral ankle sprains or exhibit significant symptoms of functional instability despite appropriate rehabilitation interventions. The goal of surgery is to restore mechanical stability to the ankle and thereby significantly reduce or eliminate chronic symptoms of instability. Late ankle reconstruction for chronic lateral instability is successful in approximately 85% of patients, regardless of the type of

surgical procedure performed [23]. Intra-articular lesions (especially syndesmotom widening), osteochondral lesions of the talus, and ossicles are predictors of unsatisfactory results of ligament reconstruction [24]. Primary anatomic repair of the anterior talofibular and calcaneofibular ligaments is the preferred method of ankle ligament reconstruction [23]. However, in cases in which there is excessive joint laxity or insufficient capsular tissue is available, reconstructions such as the Chrisman-Snook procedure with use of the split peroneal brevis tendon, the semitendinosus, or an allograft may be preferred [25,26]. If the patient has significant varus predisposing to ankle instability, a Dwyer calcaneal closing wedge or lateral calcaneal slide may be appropriate.

Potential Disease Complications

Potential long-term sequelae of chronic ankle instability include the development of ankle impingement syndrome; chronic peroneal tendinopathy or subluxation; tibiotalar osteochondral injury; degenerative arthritis; superficial peroneal neuropathy; and chronic pain syndromes, such as complex regional pain syndrome type I (reflex sympathetic dystrophy).

Potential Treatment Complications

Potential treatment complications include frostbite from overly aggressive use of ice; exacerbation of edema from inappropriate ankle taping, wrapping, or bracing; and pain exacerbation or reinjury during physical therapy. Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Surgical complications include failed repair, wound or bone infection, loss of ankle range of motion from an aggressive reconstruction, and persistent ankle pain despite appropriate rehabilitation or surgical repair or reconstruction.

Foot and Ankle Bursitis

Rathi L. Joseph, DO
Thomas H. Hudgins, MD

Synonyms

Fluid-filled sac of fibrous tissue
Glandular sac (a pouch at a joint to lessen friction)
Haglund deformity
Albert disease
Calcaneus altus
Cucumber heel
High-prow heel
Knobby heel
Prow beak deformity
Pump bump
Retrocalcaneal bursitis
Tendo Achilles bursitis
Winter heel
Hatchet-shaped heel
Achillodynia

ICD-9 Codes

726.71 Achilles bursitis or tendinitis
726.79 Retrocalcaneal bursitis
727.2 Specific bursitis often of occupational origin
727.3 Other bursitis disorders

ICD-10 Codes

M76.60 Achilles tendinitis, unspecified leg
M76.61 Achilles tendinitis, right leg
M76.62 Achilles tendinitis, left leg
M70.90 Unspecified soft tissue disorder related to use, overuse and pressure of unspecified site
M71.9 Bursopathy, unspecified

Definition

Bursae are closed sacs lined by a synovium-like membrane; they contain synovial fluid and are usually located in areas that are subject to friction. Their purpose is to mitigate friction and thus to facilitate the motion that occurs between bones and tendons, bones and skin, or tendons and ligaments [1].

Bursae are classified according to their location, as shown in Table 86.1 [1,2].

Symptomatic malleolar bursae most likely result from abnormal contact pressures. They may also be secondary to shear forces that arise between the bony malleoli and the patient's footwear, particularly boots or athletic shoes that surround the ankle. These may occur either medially or laterally. However, medial bursae are more common [1]. The bone prominences of the malleoli have little inherent soft tissue to protect them from these excessive pressures. The body responds to this abnormal stress by developing an adventitious bursa at this site. The skin and subcutaneous tissues are then able to glide over the bone prominences and thus dissipate these excessive forces. Sometimes, these bursae may become inflamed, resulting in bursitis.

The posterior heel includes the retrocalcaneal bursa, which is located between the calcaneus and the Achilles tendon insertion site, and the retroachilles bursa, which is located between the Achilles tendon and the skin. Each bursa is a potential site of inflammation. The most common cause of posterior heel bursitis is ill-fitting footwear with a stiff posterior edge that abrades the area of the Achilles tendon insertion. Retrocalcaneal inflammation may also be associated with a prominence of the posterosuperior lateral aspect of the calcaneus, causing irritation of the bursa, called a Haglund deformity or pump bump. This entity often goes hand-in-hand with retrocalcaneal bursitis, and frequently there is an element of insertional tendinitis as well.

Although Haglund deformity is more commonly found in women who wear high-heeled shoes, it is sometimes found in hockey players who wear a rigid heel counter that causes irritation. The population of patients that has this superolateral bone prominence tends to be younger than the patients with retrocalcaneal bursitis [3]. Numerous biomechanical risk factors have been associated with Haglund deformity. These include a high-arch cavus foot, rearfoot varus, rearfoot equinus, and trauma to the apophysis in childhood [4-6] (Fig. 86.1).

Table 86.1 Classification of Bursae According to Location		
Bursal Type	Examples	Description
Deep	Retrocalcaneal	Found beneath the fibrous investing fascia Develop in utero Often communicate with joints
Subcutaneous	Olecranon, prepatellar	Develop during childhood Do not normally communicate with the adjacent joint
Adventitious	Malleolar, metatarsal head	Often have a thick, fibrous wall Are susceptible to inflammatory changes

FIGURE 86.1 The anatomy of the structures around the ankle joint. (From Morelli V, James E. *Achilles tendonopathy and tendon rupture: conservative versus surgical management. Prim Care* 2004;31:1039-1054.)

Table 86.2 Risk Factors for Foot and Ankle Bursitis	
Type of Bursitis	Risk Factors
Malleolar Retrocalcaneal	Commonly found in repetitive overactivity in boot-wearing athletes, such as ice skaters Athletic overactivity associated with repetitive trauma Most common in long-distance runners who run uphill as a training method Hindfoot varus Rigid plantar-flexed first ray
Retroachilles	Commonly found in women who wear high-heeled shoes In the athletic population, it is often found in hockey players who wear a rigid heel counter that causes irritation Retrocalcaneal bursitis Achilles tendinitis High-arch cavus foot Hindfoot varus Hindfoot equinus
Metatarsal	Trauma to the apophysis in childhood First metatarsal: dancers, squash players, or skiers Second to fourth metatarsals: chronic inflammatory arthritis

Bursitis can also occur in the forefoot and may involve the intermetatarsal bursae or the adventitial bursae beneath the metatarsal heads [2].

Risk factors for foot and ankle bursitis are outlined in Table 86.2. Runners, especially those who train uphill, sustain repeated ankle dorsiflexion. Repetitive stress through this motion can lead to bursitis. Also, runners and recreational walkers with sudden increase in mileage are at risk for acquiring symptoms of tenderness, swelling, redness, and pain near the insertion of the Achilles tendon. The most common cause of ankle bursitis is tight-fitting shoes with a firm heel counter.

Women wearing high-heeled shoes, runners with improper shoe fit or overworn footwear, skaters, and patients with lower extremity edema are susceptible to development of ankle bursitis. Other important causes of bursitis, in general, are trauma, infection, rheumatoid arthritis, and gout.

Symptoms

With malleolar bursitis, there may be exquisite tenderness surrounding the inflamed bursa, a fluctuant mass over the medial malleolus, and decreased range of motion of the ankle.

Retrocalcaneal bursitis is hallmarked by pain that is anterior to the Achilles tendon and just superior to its insertion on the os calcis. Compression of the bursa between the calcaneus and the Achilles tendon occurs every time the ankle is dorsiflexed; in a runner, the repetitions are countless, particularly with uphill running, when ankle dorsiflexion is increased. Patients often develop a limp, and wearing of shoes may eventually become increasingly painful. Thus, it is not surprising that long-distance runners who use uphill running as a training method frequently develop retrocalcaneal bursitis.

Patients with retroachilles bursitis are often asymptomatic. However, when symptoms occur, the patient usually presents with a painful, tender subcutaneous swelling overlying the Achilles tendon, usually at the level of the shoe counter. The overlying skin may be hyperkeratotic or reddened.

Patients with metatarsal bursitis usually have exquisite tenderness surrounding the inflamed bursa, swelling over the metatarsal head, and decreased range of motion of the metatarsophalangeal joint.

Physical Examination

The physical examination findings in bursitis are described in Table 86.3.

The physical examination includes inspection of the patient's foot at rest and in a weight-bearing position. A visual survey of the foot may reveal swelling, bone deformities, bruising, or skin breaks. The physician should palpate bone prominences and tendinous insertions near the heel and midfoot, noting any tenderness or palpable defects. Passive range of motion of the foot and ankle joints is assessed for indications of restricted movement. Foot posture and arch

formation are visually examined while the patient is bearing weight; the physician is looking for abnormal pronation or other biomechanical irregularities. The wear pattern on the posterior interior wall of the shoe should also be examined.

In general, the site of the inflamed bursa is fluctuant and may have some mild associated tenderness and warmth. The patient should be examined closely for any erythema, edema, hypersensitivity, fever, or swollen lymph nodes to rule out septic bursitis.

Insertional tendinosis involves degeneration, not inflammation, of the most distal portion of the Achilles tendon and its attachment on the calcaneal tuberosity. Distinguishing insertional Achilles tendinosis from retrocalcaneal bursitis or osseous impingement, although desirable, is difficult because both may be a continuum of the same disease process or can coexist.

Functional Limitations

Adhesions of the surface of a bursa limit the degree of movement of the associated joint. Pain is a common cause of decreased function. The patient may be limited in ambulation, climbing stairs, and sports activity. The patient also may be limited in footwear, such as protective boots for work.

Diagnostic Studies

Careful physical examination will often yield the cause of most heel pain. Nonetheless, physicians often order radiographs to aid in the diagnostic workup and to exclude osseous causes of the pain. The radiographic findings of bursitis are listed in Table 86.4.

Table 86.3 Bursitis—Physical Findings

Type of Bursitis	Physical Findings
Malleolar	Painful, tender subcutaneous swelling overlying the malleolus Overlying skin may be hyperkeratotic or reddened.
Retrocalcaneal	Tenderness and boggy swelling along the medial and lateral aspects of the Achilles tendon at its insertion Posterior heel pain with passive ankle dorsiflexion Posterior heel pain with active-resisted plantar flexion A positive two-finger squeeze test result: pain elicited by application of pressure both medially and laterally with two fingers just superior and anterior to the Achilles insertion
Retroachilles	Painful, tender subcutaneous swelling overlying the Achilles tendon, usually at the level of the shoe counter, and on lateral side of Achilles tendon Overlying skin may be hyperkeratotic or reddened.
Metatarsal	If a superficial bursa is affected, there will be signs of acute inflammation, with fluctuant swelling and warmth. If a deep bursa is affected, tissues are tight and congested. Pain with direct pressure, compression, or dorsiflexion of the associated digit An overlying callus may suggest that this is a high-pressure site during normal gait.

Table 86.4 Bursitis—Radiographic Findings

Type of Bursitis	Radiographic Findings
Malleolar	Diagnosis is essentially clinical, and further evaluation is not required.
Retrocalcaneal	Magnetic resonance imaging shows a bursal fluid collection with low signal intensity on T1-weighted images and high signal intensity on T2-weighted and STIR images. A bursa larger than 1 mm anteroposteriorly, 7 mm craniocaudally, or 11 mm transversely is considered abnormal [7].
Retroachilles	Diagnosis is essentially clinical, and further evaluation is not required. It may be discovered incidentally at magnetic resonance imaging performed to evaluate other heel injuries. Its appearance is similar to that of retrocalcaneal bursitis and consists of a bursal fluid collection just posterior to the distal Achilles tendon.
Metatarsal	Magnetic resonance imaging shows a well-defined fluid collection at a pressure point and demonstrates low signal intensity on T1-weighted images and high signal intensity on T2-weighted and STIR images. Small fluid collections with a transverse diameter of 3 mm or less in the first three intermetatarsal bursae may be physiologic. Peripheral enhancement is with gadopentetate dimeglumine [8].

Levy and colleagues [9] demonstrated that routine radiographs are of limited value in the initial evaluation of non-traumatic plantar heel pain in adults and are not necessary in the initial evaluation. They suggested that radiographs should be reserved for patients who do not improve as expected or present with an unusual history or confounding physical findings.

Multiple studies have attempted to delineate Haglund deformity radiographically by looking at the height, length, and angular relationships of the calcaneus. Most authors cannot recommend one particular radiographic view as being consistently helpful in demonstrating this bone prominence or in making a diagnosis or planning treatment. Ultrasonography can be used to visualize an anechoic area of fluid and can be helpful in medication placement [10].

Differential Diagnosis

METATARSAL BURSITIS

Trauma
Freiberg infraction
Infection
Arthritis
Tendon disorders
Non-neoplastic masses
Neoplasms

ANKLE OR HEEL BURSITIS

Achilles tendinitis
Calcaneus stress fracture
Rheumatoid arthritis
Gout
Seronegative spondyloarthropathies
Sural neuritis

Treatment

The treatment of bursitis is summarized in [Table 86.5](#).

Initial

In general, nonoperative treatment of foot and ankle bursitis is always recommended first. Conservative treatment of heel pain, in general, includes use of nonsteroidal anti-inflammatory agents, physical therapy, and avoidance of repetitive high-impact activities [11]. If there is some associated Achilles tendon or plantar fascia disease present, a night splint may help relieve the acute pain many patients experience when they first get up in the morning.

Conservative treatment of general heel pain also includes use of heel lifts and open-back shoes. A portion of the heel counter can be cut away and replaced with a soft leather insert to cause less friction at the site where the heel counter meets the skin. Shoes without laces are to be avoided because they inherently fit close to the heel. Insertion of a heel cup in the shoe may help raise the inflamed region slightly above the restricting heel counter of the shoe. A heel cup also should be placed in the other shoe to avoid introducing leg length discrepancy. Pressure-off silicone sheet pads can be used long term when shoes with counters are worn. Custom orthoses are prescribed for those who have underlying structural abnormalities causing the symptoms.

Table 86.5 Bursitis—Treatment

Type of Bursitis	Treatment
Malleolar	Boot modification or change of footwear Doughnut-shaped cushion made to fit over malleoli
Retrocalcaneal	Rest and activity modification Rest and activity modification (e.g., avoidance of running and walking up hills and stairs) Encourage athletes to change running shoes on a regular basis Biomechanical control in the form of temporary heel lifts, tape immobilization, and, if abnormal pronation is present, custom foot orthotics Slight heel elevation with a felt heel pad A night splint to help keep the Achilles tendon and plantar fascia stretched to relieve acute morning pain and stiffness
Retroachilles	Rest and activity modification Heat application Padding Wearing a soft, nonrestrictive shoe without a counter (e.g., clogs, sandals)
Metatarsal	Rest and activity modification Protective padding Assess for any underlying deformity or foot type with abnormal function

Table 86.6 Bursitis—Rehabilitation

Type of Bursitis	Rehabilitation
Malleolar	Physical therapy is usually not necessary unless joint range of motion is affected. Physical therapy is then necessary to maintain ankle range of motion.
Retrocalcaneal	Physical therapy to teach stretching exercises of the Achilles tendon and plantar fascia Ice can be applied for 15 to 20 minutes, several times a day, during the acute period. Some clinicians also advocate use of contrast baths. Alternative means of maintaining strength and cardiovascular fitness include swimming, water aerobics, and other aquatic exercises.
Retroachilles	Physical therapy to teach stretching exercises of the Achilles tendon

Rehabilitation

The rehabilitation of bursitis is described in [Table 86.6](#).

The patient is allowed weight bearing as tolerated and should be instructed to elevate the foot when not walking. If the patient has had surgery, the dressing is removed 3 days postoperatively, and the patient is allowed to shower. The patient is encouraged to perform active range of motion exercises at least three times a day for 10 minutes each time. The patient is allowed to wear regular shoes as soon as this is tolerated.

Physical therapy is used to teach stretching exercises of the Achilles tendon and plantar fascia to preserve range of motion. This gradual progressive stretching of the Achilles tendon may help relieve impingement on the subtendinous bursa.

Stretching of the Achilles tendon can be performed in the following manner: place the affected foot flat on the floor and lean forward toward the wall until a gentle stretch is felt within the ipsilateral Achilles tendon; maintain the stretch for 20 to 60 seconds and then relax. These stretches should be performed with the knee extended and repeated with the knee flexed, as seen in Figure 86.2. For the benefit of the stretching program to be maximized, repeat for several stretches per set, several times per day. Avoid ballistic (abrupt, jerking) stretches. Progress to calf dips on a stair for functional stretching and eccentric strengthening. Contrast baths and ice massage are also used in the acute management. Icing can be performed for 15 to 20 minutes, several times a day, during the acute period.

The athlete may be expected to return to play without restrictions after demonstrating resolution of symptoms, resolution of physical examination findings (e.g., limping, tenderness on palpation), and adequate performance of sports-specific practice drills without recurrence of symptoms or physical examination findings.

Procedures

If the patient remains symptomatic or finds the bursa to be aesthetically displeasing, the bursa can be aspirated and injected with a 1- to 2-mL solution of a corticosteroid. Many clinicians prefer not to repeat this injection more than once because the risk of tendon rupture is not worth the limited benefits offered by corticosteroid injection. However, tendon rupture is a known complication when corticosteroids are injected directly into the tendon substance [12,13]. There is no available evidence suggesting an association between corticosteroid injections of ankle bursae and Achilles tendon rupture, although most practitioners believe that ultrasound guidance can decrease the possibility of injection within the tendon itself.

Surgery

About 10% of patients with retrocalcaneal or supracalcaneal bursitis do not respond to conservative treatment and seek a surgical solution [14]. Open surgical techniques focus on resection of the posterosuperior portion of the calcaneus or performance of a calcaneal wedge osteotomy with or without débridement of diseased Achilles tendon. Endoscopic techniques provide visualization of the tendon-bone relationship with endoscopic inspection and allow precise débridement and evaluation for residual impingement. The smaller access allows easier closure and less extensive postoperative care. The small incision minimizes the potential for wound dehiscence, a painful scar, and nerve entrapment in scar tissue, and it provides a cosmetically superior result. Endoscopic techniques have had higher patient satisfaction and lower complication rates than open surgical treatment [15].

Potential Disease Complications

The primary disease complication is chronic bursitis with intractable pain that may limit footwear and joint mobility. Adhesive bursitis is another potential disease complication that may occur with chronic bursitis. In adhesive bursitis,

FIGURE 86.2 Stretching of the ankle plantar flexors. **A**, Gastrocnemius muscle. **B**, Soleus muscle. (From Muscolino JE. *The Muscle and Bone Palpation Manual with Trigger Points, Referral Patterns, and Stretching*. St. Louis, Mosby, 2009.)

two adjacent layers of the bursa may adhere and significantly decrease joint range of motion.

The course of bursitis may also be complicated by infection causing a septic bursitis. In this case, immediate surgical débridement and intravenous antibiotics are indicated. A *Staphylococcus aureus* organism is most often responsible and should be treated with appropriate antibiotics.

Potential Treatment Complications

Risks of chronic nonsteroidal anti-inflammatory drug use include gastrointestinal bleeding, renal toxicity, hypertension, and other cardiovascular complications; thus, duration should be kept to a minimum. Systemic complications may be lessened by use of topical nonsteroidal anti-inflammatory drugs to the affected area only.

Complications of open, endoscopic, and fluoroscopic surgical procedures include skin breakdown, avulsion of the Achilles tendon, inadequate decompression with recurrent pain, sensitive and disfiguring scars, altered sensation, and stiffness. In one series, open treatment was associated with a 14% rate of infection, a 17% rate of wound breakdown, a 23% rate of scar tenderness, and a 38% rate of altered sensation [16].

The role of corticosteroid injections in the treatment of retrocalcaneal bursitis is controversial. There have been numerous case reports of patients who have sustained a tendon rupture after peritendinous injections of corticosteroids for the treatment of tendinitis or tendinosis; however, little has been reported on retrocalcaneal intrabursal injections for the treatment of bursitis. Martin and associates [17] investigated the mechanical properties of and histologic changes in rabbit Achilles tendons after peritendinous steroid injection. They found that local injections of corticosteroid, both within the tendon substance and into the retrocalcaneal bursa, adversely affected the biomechanical properties of rabbit Achilles tendons. Another animal study also showed adverse effects of local injections of corticosteroid (within the tendon substance and into the retrocalcaneal bursa) on the biomechanical properties of Achilles tendons [18].

Prolonged immobilization may result in adhesions and subsequent joint stiffening. Thus, patients should have early mobilization after low-grade ankle sprains to prevent increased risk of ankle bursitis.

Patients with ankle bursitis may benefit from accelerated rehabilitation within 7 days of injury to improve muscle strength, sensorimotor control, and range of motion, much like patients after ankle sprains [19], but this has not yet been studied.

Hallux Rigidus

David Wexler, MD, FRCS (Tr & Orth)

Dawn M. Grosser, MD

Todd A. Kile, MD

Synonyms

Osteoarthritis or degenerative joint disease of the first metatarsophalangeal joint
Osteoarthritis of the great toe [1]

ICD-9 Code

735.2 Hallux rigidus

ICD-10 Codes

M20.20 Hallux rigidus, unspecified foot
M20.21 Hallux rigidus, right foot
M20.22 Hallux rigidus, left foot

Definition

Degenerative joint disease or loss of articular cartilage from the first metatarsophalangeal (MTP) joint leading to painful restriction of motion is called hallux rigidus. The normal range of motion of the first MTP joint is 30 to 45 degrees of plantar flexion to almost 90 degrees of dorsiflexion. The limited range of motion and pain with hallux rigidus are exacerbated by overgrowth of bone (osteophytes or “bone spurs”) on the dorsal aspects of the base of the proximal phalanx and the head of the metatarsal, which impinge on one another as the great toe dorsiflexes [2]. Hallux rigidus is the second most common problem in the first MTP joint, after hallux valgus; 1 in 40 people older than 50 years will develop hallux rigidus [3].

In general, the cause is unknown, although it is associated with generalized osteoarthritis of other joints and repeated microtrauma (e.g., in soccer players). Sustaining repetitive turf toe–type injuries may lead to this form of early joint degeneration [4]. As the plantar capsuloligamentous complex of the first MTP joint is injured by hyperflexion of the great toe, it may acutely compress the articular surfaces of

the joint, causing articular damage, or become chronically unstable, predisposing the MTP joint to degeneration and hallux rigidus [5].

Symptoms

Patients typically report pain, either intermittent or constant, that occurs with walking and is relieved by rest. It is insidious in onset and may be associated with stiffness, swelling, and sometimes inflammation. On occasion, there can be locking due to a cartilaginous loose body. Patients may notice that they are walking on the outside of the foot to avoid pushing off with the great toe during the terminal stance and toe-off phases of the gait cycle. As degeneration increases, the pain may intensify and result in an alteration of gait.

Physical Examination

On inspection, there will usually be swelling around the MTP joint with tenderness of the joint line. Dorsal osteophytes may be palpable and may cause irritation of overlying skin with shoe wear abrasion. Pain is reproduced with forcible dorsiflexion of the great toe, which is also restricted in range of movement. Plantar flexion may also be affected. Patients may have an antalgic (painful) gait, and single-stance heel raise may be difficult secondary to a painful MTP joint, as opposed to posterior tibial tendon deficiency. Findings of the neurologic examination, including strength, sensation, and reflexes, are typically normal.

Functional Limitations

Functional limitations include walking long distances, running any distance, and ascending stairs. As the severity increases, walking even short distances, daily errands, and standing for long periods may be difficult. Flexible shoes as well as shoes with a tight toe box may prove to be uncomfortable. This may lead to pressure areas dorsally over the osteophytes.

Diagnostic Studies

Plain anteroposterior and lateral standing radiographs will usually suffice in confirming the diagnosis (Fig. 87.1).

FIGURE 87.1 Standing anteroposterior radiograph of both feet. This demonstrates bilateral hallux rigidus or degenerative joint disease of the hallux MTP joints. The signs are narrowing of the joint space, osteophyte formation, and sclerosis. This is more pronounced on the right.

The signs are consistent with degenerative joint disease, namely, loss of joint space and congruency, large dorsal osteophytes (bone spurs), sclerosis (increased density of bone), and subchondral cysts. There may be evidence of a loose body. This disease process has been divided into three grades on the basis of the severity of radiographic and clinical findings, which help guide surgical treatment.

Grade I demonstrates small dorsal osteophytes with preservation of the MTP joint space on radiographic examination and typically intermittent pain with ambulation. Grade II demonstrates moderate dorsal osteophyte formation and asymmetric joint space narrowing radiographically and often constant pain with ambulation. Grade III has extensive osteophytes and severe dorsal and plantar joint space narrowing, often with noticeable loose bodies; clinically, patients will have constant pain with ambulation and significant limitation of motion [6].

Differential Diagnosis

- Gout
- Hallux valgus
- Turf toe
- Fracture

Treatment

Initial

Nonsteroidal anti-inflammatory drugs may provide symptomatic relief. Footwear modifications and orthoses to limit stresses at the MTP joint (carbon fiber inserts or Morton's extension orthotic devices) as well as avoidance of high

heels or shoes with very flexible soles may be useful conservative treatment options [7].

Rehabilitation

More advanced shoe modifications can be made by a certified pedorthist. These include a steel shank and possibly a rocker-bottom. These may be applied to the soles of many different types of shoes, including athletic shoes. Anecdotally, many patients prefer first to try a steel shank because there is no cosmetic change to the shoe. With a rocker-bottom, the sole is altered, and this is sometimes less cosmetically acceptable to patients.

If there is evidence of other foot deformities, such as pes planus (flatfoot), orthotic inserts may provide correction and help with gait biomechanics.

Physical therapy is not generally necessary but may include basic mobilization and distraction techniques as well as strengthening exercises of the flexor and extensor hallucis muscles to enhance joint stability. Modalities such as contrast baths and ice may help with pain control.

Procedures

Intra-articular x-ray-guided or ultrasound-guided injection of the MTP joint with local anesthetic and steroid may provide short-term relief.

Surgery

The principal indications for surgery are continuing pain and failed nonoperative management. Depending on the severity of the degeneration, there are two broad approaches to surgery. For grade I and grade II, the appropriate treatment is joint preserving; the impinging dorsal osteophytes are excised and the joint is debulked, thus improving dorsiflexion [8–10]. A phalangeal osteotomy (i.e., Moberg procedure) may also be used to improve dorsiflexion. The second approach is joint sacrificing for grade III disease. These procedures range from resection arthroplasty, resulting in a floppy or flail shortened toe, to arthrodesis (Fig. 87.2), resulting in a stiff, rigidly fixed toe [6,11,12]. A number of manufacturers have tried to produce artificial great toe joints, made of Silastic, metal, and polyethylene or ceramic [13,14], but the long-term results of these have not lived up to expectations. A randomized controlled trial comparing arthrodesis to arthroplasty found better improvement in pain, satisfaction of patients, and cost ratio with arthrodesis. Patients receiving arthroplasty had minimal improvement in range of motion, had continued altered gait mechanics, and required removal secondary to loosening in a significant number [15]. Interposition arthroplasty (with use of autologous tissue attached between the two joint surfaces) has also been advocated as a reasonable option instead of fusing the joint for grade III disease [16]. Arthroscopic surgery has also been attempted.

Potential Disease Complications

Hallux rigidus may produce intractable pain and reduced mobility.

FIGURE 87.2 Standing anteroposterior radiograph of both feet. This demonstrates, on the left foot, one of the techniques for fusing the MTP joint, with crossed cannulated screws. The right foot shows a hallux valgus deformity.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Steroid injection can rarely introduce infection.

Complications of surgery can range from failure of improvement with insufficient osteophyte resection to toe shortening with subsequent transfer metatarsalgia (pain under the metatarsal heads of the lesser toes). Arthroplasty complications include implant failure, silicone wear and subsequent debris production, foreign body reaction, and osteolysis. Arthrodesis complications include malunion and nonunion.

M20.5X2 Other deformities of toe(s) (acquired), left foot
M20.5X9 Other deformities of toe(s) (acquired), unspecified foot

Definition

Hammer toe refers to an abnormal flexion posture at the proximal interphalangeal (PIP) joint of one or more of the lesser four toes [1]. If the flexion contracture is severe and of long duration, concomitant hyperextension of the metatarsophalangeal (MTP) joint and extension of the distal interphalangeal (DIP) joint may occur (Fig. 88.1). In contrast to clawing, which tends to involve all toes, hammer toe deformity usually affects only one or two toes [2]. Hammer toes are classified as either flexible (passively correctable) or rigid (not passively correctable to the neutral position). The most commonly affected toe is the second, although multiple digits can be involved [3].

Hammer toe is the most common of the lesser toe deformities and occurs primarily in the sagittal plane. It is arguably the most common toe disorder that presents to the foot and ankle surgeon's office. Women are more commonly affected, and the incidence of hammer toe increases with age [4–6].

Contributing factors include long-term wear of poorly fitting shoes, especially those with tight, narrow toe boxes. Crowding and overlapping from hallux valgus are other causes. A long second ray with subsequent buckling of the toe may also lead to the deformity. Other predisposing factors are diabetes, connective tissue disease, and trauma [5].

Symptoms

Patients commonly complain of pain or tenderness in the area of the PIP joint, especially when wearing shoes or during weight-bearing activities. Patients also commonly present with cosmetic complaints. Pain may be the result of corn or callus formation over the dorsal aspect of the PIP joint from shoe compression. In cases in which hyperextension of the MTP joint has occurred, there is also increased pressure under the metatarsal heads. Metatarsalgia with subsequent callus formation underneath the metatarsal heads may occur secondary to their plantar displacement [2], with distal displacement of the plantar fat pad.

Physical Examination

The diagnosis is confirmed by the presence of MTP joint hyperextension, PIP joint flexion, and DIP joint extension in the affected toe. Palpation of the PIP joint usually causes tenderness, with the plantar aspect more commonly affected.

On inspection, determine the degree of PIP flexion. Also note accompanying foot deformities, such as ulcerations and callus formation over the PIP joint and tip of the toe. Hammer toe deformities become more prominent in stance phase. Examination of the joint range of motion of the affected toe will differentiate a fixed deformity from the one that is flexible. The presence or absence of crepitus should be noted. Flexor digitorum longus contracture is assessed with the ankle in dorsiflexion and plantar flexion. Correction of the deformity on plantar flexion signifies a flexible hammer toe. Dorsiflexion, in turn, accentuates the deformity [7].

The Kelikian push-up test is used to assess the degree of flexibility. Press upward on the plantar aspect of the

FIGURE 88.1 Diagrammatic representation of hammer toe. (From Krug RJ, Lee EH, Dugan S, Mashey K. Hammer toe. In Frontera WR, Silver JK, Rizzo TD Jr, eds. *Essentials of Physical Medicine and Rehabilitation*, 2nd ed. Philadelphia, WB Saunders, 2008.)

metatarsal head; in flexible deformities, the MTP joint will align and the proximal phalanx will assume a more normal position.

A mild deformity hammer toe implies no fixed contracture at the MTP or PIP joint, but the deformity increases with weight bearing. A moderate deformity hammer toe has a fixed or partially fixed contracture at the PIP joint and zero to mild extension contracture at the MTP joint. A severe deformity hammer toe involves fixed flexion contracture at the PIP joint with a fixed extension contracture of the MTP joint. Subluxation or dislocation of the proximal phalanx on the metatarsal head may also be present [7].

Also assess for signs of swelling, temperature change, or erythema that might indicate the presence of an infectious or rheumatic process responsible for the deformity.

Inspection of the patient's footwear is necessary to determine the ability of the toe box to accommodate the forefoot. The presence of corns or callus over the PIP joint, which may ulcerate, is often indicative of poorly fitting footwear.

Standard neurologic and vascular examinations will reveal no abnormal findings in uncomplicated hammer toe deformities. If there is a superficial peroneal nerve injury causing a dropfoot deformity, hammer toes will result because of extensor substitution. Likewise, a weakness of the gastrocnemius can lead to flexor substitution, causing a hammer toe.

If the patient has peripheral vascular disease or atherosclerosis, ulceration over a PIP joint may lead to toe loss unless the toe is revascularized.

Functional Limitations

Functional limitations mostly result from pain incurred by corn and callus formation. Walking and other weight-bearing activities can be painful. The ability to tolerate footwear with a narrow toe box is also impaired.

Diagnostic Studies

The diagnosis is primarily a clinical one. However, radiographs can be useful in the assessment of a rigid hammer toe, with weight-bearing views preferred. An apparent joint space narrowing on the anteroposterior view corresponds to subluxation of the proximal phalanx on the metatarsal head at the MTP joint [5,7].

Differential Diagnosis

- Claw toes
- Mallet toes
- Interdigital neuroma
- Nonspecific synovitis of the metatarsophalangeal joint
- Triggering of the lesser toes (lower limb analogue of trigger finger) [8]
- Rheumatoid or psoriatic arthritis
- Plantar plate rupture

Treatment

Initial

Patient education is critical. The first step involves fitting for shoes with an adequate toe box to accommodate the dorsiflexed position of the proximal phalanx. High heels should be avoided as much as possible. A soft insole can also be used, which is useful for pressure relief [8]. Oral or topical nonsteroidal anti-inflammatory drugs (NSAIDs) can help with pain and inflammation. Analgesic medications may be taken for pain relief. Ulcer and callus management may be necessary, and patients should be educated about monitoring their skin for breakdown, especially in the setting of peripheral neuropathy.

Local icing may also help with acute pain (10 minutes, two or three times a day). However, ice should be avoided in patients with significant peripheral vascular disease because of its vasoconstrictive properties and in individuals with impaired sensation, such as peripheral neuropathy, because of the risk of frostbite.

Initial treatment is palliative rather than corrective and predominantly consists of attempts to accommodate the toe deformity by changing the patient's footwear and débridement of calluses if they are present. This may include stretching the shoes or switching to shoes with a deeper toe box or to extra-depth shoes. Padding, such as toe crest pads or custom or premade hammer toe regulators, may relieve pressure over the involved joints. Patients with calluses on the PIP joint may benefit from digital caps or silicone cushions.

Rehabilitation

Formal physical therapy is usually not required, although some patients might benefit from a supervised paraffin treatment, which should be followed by stretching exercises. Paraffin baths are contraindicated if ulcers or sensory deficits are present [9].

Stretching exercises can relieve the "tight" sensation in patients with a flexible or semiflexible deformity. Exercises such as picking up a towel with the toes are recommended for both stretching and strengthening of the intrinsic foot muscles.

Functional orthotics will provide flexor stabilization and, in some instances, symptomatic relief to overpronators with a flexible hammer toe deformity. Orthotics may slow the progression of the deformity by improving the biomechanics of the feet.

The clinician may prescribe shoes with deep, wide toe boxes. Alternatively, extra depth can be achieved in

a standard shoe by trimming the existing shoe insert just distal to the metatarsal heads [10]. Lambswool or felt around the toes provides extra padding. An external metatarsal bar and rocker-bottom shoes may provide additional comfort-enhancing options. Specific strapping devices and hammer toe straightening orthoses are available. Again, patients with peripheral vascular disease or neuropathy should be cautious or avoid these.

Procedures

Steroid injections may be indicated for patients with painful PIP joint capsulitis or arthritic flare secondary to a hammer toe deformity. Combine steroid injections with padding or splinting for optimal relief. By use of a 27-gauge needle and corticosteroid with local anesthetic mixture, introduce the solution into the joint capsule through the dorsomedial or dorsolateral aspect of the joint. Always perform a surgical preparation before injecting the joint. The patient should be advised about the possibility of a steroid flare.

Surgery

Operative treatment should be pursued when conservative treatment fails. Cosmesis alone is not a good indication for surgery. Associated deformities must also be corrected for optimal surgical outcome (e.g., hallux valgus) [7].

Multiple procedures have been described for the surgical management of hammer toes. The procedures used are based on the degree of hammer toe deformity. A stepwise approach involving several procedures may be needed to accomplish correction on the basis of severity. Outcomes are varied by the specific procedures chosen. The following procedures are most commonly recommended and data supported [2]:

Mild deformity/flexible hammer toe (no fixed contracture at the MTP or PIP joint): flexor to extensor transfer using flexor digitorum longus.

Moderate deformity/rigid hammer toe with MTP subluxation (fixed flexion contracture at the PIP; MTP subluxation in extension): resection of the condyles of the proximal phalanx, dermodesis (removal of an ellipse of skin on the volar aspect of the joint); lengthening of extensor digitorum longus, tenotomy of extensor digitorum brevis; MTP capsulotomy, collateral ligament sectioning.

Moderate to severe deformity/rigid hammer toe with MTP dislocation: similar to subluxation treatment with addition of MTP arthroplasty or Weil osteotomy.

Severe deformity/crossover toe (fixed flexion contracture at the PIP joint; MTP subluxation in varus or valgus): resection of the condyles of the proximal phalanx, dermodesis; collateral ligament/capsular repair; extensor digitorum brevis transfer [2,11].

Replacement of the PIP or MTP joint with toe deformity is another option, as are implants that have been developed for intramedullary placement to stabilize the PIP joint, promoting fusion. Such implants are not universally accepted and are exceedingly difficult to remove should the surgery fail. Their removal could lead to substantial bone loss, making subsequent revision procedures challenging.

Kirschner wires are usually used to stabilize the hammer toes for several weeks and are most accepted at this time.

Postoperative Rehabilitation

After 2 or 3 days of elevation of the foot, patients can bear weight as tolerated. Surgical shoes with limited activity and use of crutches are recommended for approximately 4 weeks postoperatively. If Kirschner wires are used, they are typically removed between 3 and 6 weeks after operation. This varies by the surgeon's preference [12]. Patients can start to gradually increase activities at approximately 8 weeks after surgery. More weight-bearing activities, such as running, are best started after 12 weeks of recovery. Such recommendations vary according to the severity of the deformity and complexity of the surgery.

Potential Disease Complications

Potential disease complications include chronic intractable pain that limits all mobility. Other complications may include metatarsalgia, plantar and point of contact ulcerations in the insensate foot, arthralgia and joint stiffness if subluxation has occurred, toenail deformities, and bursitis or synovitis [5]. Gait abnormalities may contribute to more proximal pain symptoms (e.g., low back and hip pain).

Diabetic neuropathy and advanced peripheral vascular disease are relative contraindications to splinting [13] when correction is nonsurgical.

Common potential complications include PIP joint ulceration due to excessive pressure, fixed foot deformity, and postural changes resulting from pain-induced gait deviations.

Potential Treatment Complications

Local icing can cause vasoconstriction and frostbite. Analgesics, NSAIDs, and cyclooxygenase 2 inhibitors have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Newer topical NSAIDs may have fewer side effects because of less systemic absorption. Postsurgical complications include toe ischemia, digital nerve palsy, nonunion, malalignment, reduced toe range of motion, rigid and excessively straight toe, persistent edema, flail toe, and osseous regrowth. Potential complications of surgical correction include flail or "floppy" toes, which can be repaired by collateral ligament repair or arthrodesis. Infection and, in severe cases, osteomyelitis can occur either before or as a complication of surgery. If intravenous antibiotic treatment is unsuccessful, partial or total toe amputation may be required. Because of the morbidity associated with surgical complications, appropriate patient selection is imperative in recommending operative correction of hammer toe deformities.

ICD-10 Codes

K59.4 Proctalgia fugax
M53.3 Coccydynia

Definition

Coccydynia is pain in the vicinity of the coccygeal bone at the base of the spine. It may be localized to the lower sacrum, the coccyx, or the adjacent muscles or soft tissues. Pain can be insidious or sudden in onset. Symptoms are usually triggered by sitting or rising from a sitting position.

The mean age at onset of coccydynia is 40 years, but it can occur over a wide range of ages [1]. The most common inciting factor is trauma to the coccyx or surrounding soft tissue from a vertical axial blow or cumulative trauma from a difficult vaginal delivery. Pathologic features may range from dislocated sacrococcygeal fracture to ligamentous damage of the caudal coccygeal segments. In most cases, the tip of the coccyx is subluxated or hypermobile [1] (Figs. 98.1 and 98.2).

The coccyx consists of three to five rudimentary vertebrae. The first coccygeal segment has transverse processes that articulate and occasionally fuse with the sacrum. This vertebra is usually separate from the remaining coccygeal

vertebrae, which may partially or completely fuse, leading to anatomic variation of one to four total bony coccygeal segments [2].

The fibrous sacrococcygeal symphysis connects the sacrum to these segments of the coccyx. This joint is reinforced by sacrococcygeal ligaments, which enclose the final intervertebral foramen through which the S5 roots exit. The S4, S5, and coccygeal roots contribute to the coccygeal plexus, which provides rich somatic and autonomic innervation to the anus, perineum, and genitals [3]. The levator ani (innervated by S3-S5 nerve root branches through perineal and inferior rectal nerve branches of the pudendal nerve [4]) and coccygeal muscles (innervated by S3-S5 nerve root branches [5]) attach to and support the coccyx during defecation and childbirth. The gluteus maximus also attaches to the lateral coccyx and can contribute to a sensation of pressure while sitting.

Morphology of the coccyx may have a role in coccydynia. The coccyx that is markedly curved or angled forward, is anteriorly subluxed [2], or contains a bone spicule [6] is more prone to pain. Degeneration of disc structures [7] and referred pain from lumbar disc disease [2] have been implicated. There are also reported cases of rare coccydynia pathologic processes, including tuberculosis, tumors, and calcification of the joints or tendons. Prevalence of coccydynia is four to five times higher in women than in men [8,9]. In addition to obstetric trauma [10], the increased susceptibility to injury in women is attributed to anatomy as the female coccyx is more posterior in location and larger than the male coccyx [11]. Coccydynia is three times more frequent in obese women than in nonobese women [6], and this may be related to decreased pelvic rotation while sitting.

Symptoms

Coccygeal pain is located at the tip or sides of the coccyx. The quality of pain is usually dull and achy at baseline and intermittently sharp during activities that aggravate the symptoms. A sensation of pressure or an urge to defecate is also commonly described. Coccydynia has been associated with dyspareunia, dyschezia, dysmenorrhea, and piriformis syndrome. Symptoms are usually exacerbated by sitting on hard surfaces, prolonged sitting, and moving from the sitting to the standing position. Symptoms are generally relieved by taking weight off the coccyx.

Levator ani syndrome and proctalgia fugax are variants of coccydynia.

FIGURE 89.1 Mallet toe (arrow indicates usual area of hyperkeratosis or ulcer formation). (From Maguire S. Mallet toe. In Frontera WR, Silver JK, Rizzo TD Jr, eds. *Essentials of Physical Medicine and Rehabilitation*, 2nd ed. Philadelphia, WB Saunders, 2008.)

high-impact activities such as running may be altogether too painful. Women may complain that they are unable to wear shoes (dress and high heeled) required for their work environment. Painless deformity generally neither causes functional limitations nor requires treatment [5].

Diagnostic Studies

The diagnosis of a mallet toe is primarily clinical. However, foot radiographs can be useful in assessing the DIP joint with fixed deformity resulting from traumatic, degenerative, or inflammatory arthritis. Weight-bearing views are preferred in assessing for functional or dynamic (versus fixed) deformity. Non-weight-bearing isolated or magnification toe views also may be helpful. Noninvasive arterial studies (toe-brachial index) are used to assess perfusion in cases in which ischemia is suspected before initiation of conservative and especially surgical treatment.

Differential Diagnosis

Claw toe
Hammer toe
Cock-up toe
Triggering of the lesser toes (lower limb analogue of trigger finger) [6]
Rheumatoid arthritis
Psoriatic arthritis

Treatment

Initial

Patient education to provide an understanding of the deformity and proper footwear are essential. Shoes fabricated with soft upper material and having (or modified to achieve) adequate toe box depth to accommodate the deformity should be recommended (e.g., extra-depth shoes). Shoes incompatible with the deformity, especially high heels, should be avoided as much as possible. A soft shoe insole may be helpful in relieving pressure at the distal aspect of the toe [7,8]. Moleskin or adhesive felt padding may be applied to painful corns, but the use of medicated (salicylic acid) plasters should be avoided, especially in patients with diabetes or peripheral vascular disease. Oral nonsteroidal

anti-inflammatory drugs and analgesics can help reduce pain but should be used only as a short-term measure. Initial care should be palliative and not directed toward deformity correction. Orthodigital devices (custom, premade, or hand fashioned), such as crest pads or mallet toe regulators, may relieve pressure over the involved joint or distal aspect of the toe, resulting in passive realignment of flexible deformities. Painful corns may be treated with digital cps, sleeves, or silicone cushions. Superficial ulcers developing from a corn or clavus are treated with off-loading measures and local wound care. Patients with “high-risk” neuropathic or dysvascular feet should be educated to perform diligent daily inspection for skin breakdown.

Rehabilitation

Formal physical therapy is usually not required unless the toe deformity is accompanied by more global foot deformity due to a neuromuscular disorder. Although toe and foot flexor tendon stretching exercises are generally of little or no benefit, they may relieve the “tight” sensation in patients with a flexible or semirigid deformity. Functional foot orthoses can provide flexor tendon stabilization and, in some instances, symptomatic relief in patients with subtalar joint hyperpronation and flexible mallet toe deformity. In occasional cases, when extra-depth shoes provide insufficient toe box room to accommodate the deformity, custom shoes may be prescribed. Physical therapy after surgical correction is usually indicated for reduction of edema.

Procedures

Steroid injections may be indicated for patients with a painful mallet toe deformity in the presence of inflammatory joint disease (Fig. 89.2). An intra-articular injection of a soluble corticosteroid with local anesthetic mixture, performed in sterile technique with a 27- or 30-gauge needle, may provide temporary relief. The patient should be advised about the possibility of a postinjection flare.

Surgery

Operative treatment should be considered when conservative treatments fail, painful cutaneous lesions persist, and especially if ulceration or infection develops. Cosmesis alone is a poor indication for surgical correction. Surgical treatment depends on the etiology, extent, and severity of the deformity. Contributory or associated digital or forefoot deformities

FIGURE 89.2 Injections are directed inside the distal interphalangeal joint, as indicated in the illustration.

(e.g., hallux valgus, hammer toe, neighboring underriding or overlapping toe deformities) may also require correction for optimal surgical outcome, including surgery for proximal interphalangeal joint flexion or metatarsophalangeal joint deformity of the same toe. For mild, flexible, manually reducible deformity, soft tissue procedures, such as long flexor tenotomy with or without plantar DIP joint capsulotomy, are indicated. For more severe and rigid deformity, DIP joint osseous and articular procedures (e.g., resection arthroplasty, arthrodesis, extension block method [9]) are required. Lesser toe mallet deformity does not absolutely require fusion [10]. Severe deformity, with the presence or threat of ulceration, may require partial digital amputation [11–13]. Cases involving osteomyelitis of the distal phalanx almost always require amputation at some level of the toe. In severe deformities, retrospective studies have shown that DIP joint resection arthroplasty combined with flexor tenotomy increases the likelihood of a good outcome [11,13]. Digital interphalangeal joint arthrodesis procedures may be performed in end-to-end or peg-in-hole fashion. The peg-in-hole technique has the advantage of shortening, which can reduce long flexor tendon tension. Temporary percutaneous 0.045-inch K-wire fixation of an end-to-end arthrodesis may result in better outcome.

Potential Disease Complications

Potential disease complications include mobility-limiting, chronic, intractable pain; metatarsalgia; dorsal or distal hyperkeratotic lesions or ulcerations, most commonly in the insensate foot; joint pain and stiffness; toenail deformities; bursitis; and synovitis. Gait abnormalities (antalgic) may contribute to more proximal pain of the low back, hip, and knee. A potential complication of nonsurgical treatment is deviation of the toes, especially overlapping second toes.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the

gastric, hepatic, and renal systems. Potential complications after corticosteroid injections include skin hypopigmentation at the injection site, infection, transient elevated blood glucose concentration, and postinjection flare (pain). Postsurgical complications include toe ischemia, digital nerve palsy, arthrodesis nonunion, joint malalignment, rigid or excessively straight toe, flail DIP joint, persistent or chronic toe edema, infection, flail toe, and periarticular osseous proliferation.

M77.9 Enthesopathy, unspecified

Definition

Metatarsalgia refers to pain in the forefoot under the metatarsal head region. Primary metatarsalgia is generally considered the result of mechanical overload of the metatarsal heads, whereas secondary metatarsalgia often has a rheumatic etiology. Primary metatarsalgia may be caused by hallux valgus, hallux rigidus, or sagittal plane first ray hypermobility, which causes a transfer of load to the lateral forefoot and lesser metatarsal heads (Fig. 90.1). A hammer toe with an associated dorsal contracture of a metatarsophalangeal (MTP) joint will cause a retrograde plantar flexion force on the metatarsal head (Fig. 90.2). Bunion surgery, with first metatarsal osteotomy resulting in excessive shortening or elevation of the first metatarsal and with resection of the base of the proximal phalanx of the hallux, is an iatrogenic cause of metatarsalgia [1]. Ankle equinus, leg length discrepancy, scoliosis, kyphosis, neuromuscular disorders, lower extremity trauma, or other foot surgery (elective or post-traumatic) may also result in increased forefoot pressures. Wearing of thin-soled high-heeled shoes may increase the risk for development of metatarsalgia. Although the relative risk of running barefoot or in “minimalist” shoes (compared with traditional running shoes) and developing

metatarsalgia is not known, a case series of experienced runners who developed metatarsal stress fractures after transitioning to minimalist running footwear was recently reported [2]. Lieberman [3] has pointed out that runners who transition to barefoot or minimalist shoes may not have strong enough extensor muscles or metatarsal bones, which could lead to an increased risk of metatarsalgia or metatarsal stress fractures.

Secondary metatarsalgia has been associated with rheumatoid arthritis, psoriatic arthritis, reactive arthritis, and systemic lupus erythematosus. MTP joint synovitis may lead to weakening or rupture of the stabilizing structures around the joint, leading to dorsal subluxation of the toes on the lesser metatarsal heads [4]. Degenerative arthritis of the lesser MTP joint may be caused by Freiberg infraction (metatarsal head avascular necrosis).

Symptoms

Plantar forefoot pain is generally aggravated by weight bearing, is often worse during the propulsive phase of gait, and is often localized beneath the second metatarsal head or second MTP joint. Lesser MTP joint morning stiffness may be present. Neuritic radiating pain may occur from irritation, inflammation, or tethering of neighboring plantar intermetatarsal nerves.

Poorly defined pain in the forefoot is a common early symptom in patients with rheumatoid arthritis. Other symptoms include MTP joint symmetric swelling and stiffness after rest.

Physical Examination

The forefoot examination attempts to elicit pain on palpation directly beneath the metatarsal heads or MTP joints, commonly the result of mechanical overload from an unstable first ray or medial column. Pain elicited with lateral compression of neighboring metatarsal heads also suggests a plantar intermetatarsal neuroma. Stress fractures are commonly identified at the metatarsal neck, demonstrated by swelling, palpable pain, or bone fixation callus. Evaluate the excursion and pain of MTP joint passive range of motion and note the presence of swelling. Assess for first metatarsal hypermobility by applying a dorsiflexion force under the first metatarsal head. If hypermobility is present, the first metatarsal head will rise well above the second metatarsal head [5]. Examine for dorsal translation of the proximal phalangeal base on the

FIGURE 90.1 Cross-sectional view of metatarsal heads. Elevated first metatarsal head results in mechanical overload of lesser metatarsal heads.

FIGURE 90.2 Hammer toe with associated plantar plate tear. The hammer toe causes a retrograde plantar flexion force on the metatarsal head.

metatarsal head (drawer test) to identify plantar plate or capsule disruption. Also check for Mulder sign, which may suggest a plantar intermetatarsal neuroma.

While the patient is standing, note the presence of forefoot deformities including hallux valgus, hammer toes, MTP joint dorsal contractures, and medial or lateral subluxation of the toes. The “paper pull-out test” to evaluate toe purchase is performed by asking the patient to flex the toe against a piece of paper placed on the floor under the toe. The test result is positive if the paper cannot be pulled out from under the toe. If there is a V-shaped alignment of adjacent toes noted while the patient is standing, indicative of web space widening, early synovitis [6], plantar intermetatarsal neuroma, or other space-occupying mass may be present. Weight-bearing bilateral or unilateral heel raise while standing barefoot often aggravates metatarsalgia pain. During gait examination, observe for early heel-off, antalgic gait, excessive or insufficient subtalar joint pronation, asymmetry, and lack of toe purchase. Inspect the skin for plantar calluses and their locations. Examine the shoe outsoles and insoles for signs of excessive or uneven wear indicative of areas of elevated pressure or abnormal foot mechanics.

Functional Limitations

Forefoot pain may limit standing, walking, and participation in high-impact activities, such as running or jumping. There will be a limitation to shoe style able to be worn comfortably. Metatarsalgia has its greatest impact on activities requiring prolonged standing or walking on hard floors (e.g., cashier, food

preparation, or housekeeping jobs). Sales jobs requiring use of a dress shoe may be difficult. Walking speed may decrease while shopping or accessing public transportation. Recreational activities, such as walking, tennis, basketball, or running on a treadmill on an incline, may be particularly painful.

Diagnostic Studies

Weight-bearing foot radiographs will demonstrate the relative lengths of the metatarsals and transverse plane splaying, if it is present. A forefoot axial view may reveal a structural abnormality of the metatarsal head condyles or relative prolapse of a metatarsal head due to plantar flexion. Metatarsal stress fractures may be identified, but less so on initial radiographs, which may appear unremarkable. Radiographs may also reveal a displaced fracture, foreign body, and stigmata of tumor, osteomyelitis, and noninflammatory or inflammatory arthritis. Ultrasonography and magnetic resonance imaging may be used to evaluate inflammatory arthritis, MTP joint plantar plate disruption, early stress fracture, ligament or tendon tear, abscess, and plantar intermetatarsal neuroma. Laboratory tests may be ordered if inflammatory arthritis or infection is suspected. Although it is not widely used in the office setting, dynamic pedobarography including in-shoe pressure distribution measurement systems may reveal subtle regions of excessive plantar pressure and be used to monitor treatment results.

Differential Diagnosis

- Bursitis (intermetatarsal or plantar metatarsal head)
- MTP joint synovitis
- Flexor tendon sheath synovitis
- MTP joint capsulitis
- MTP joint plantar plate rupture
- Inflammatory and noninflammatory arthritis
- Freiberg infraction
- Intermetatarsal plantar neuroma
- Metatarsal stress fracture
- Infection (abscess or osteomyelitis)
- Plantar callus
- Intractable plantar keratoma
- Plantar wart (verruca plantaris)
- Foreign body
- Neoplasm (soft tissue or bone)
- Radiculopathy (lumbosacral)
- Tarsal tunnel syndrome
- Peripheral neuropathy or neuritis
- Claudication

Treatment

Initial

Focal plantar pressure can be reduced by applying a felt or foam rubber aperture pad to off-load a single metatarsal head, or a foam rubber or felt metatarsal pad or bar may be applied just proximal to a single metatarsal head or multiple neighboring metatarsal heads. Prefabricated pads are commercially available. The pads may be applied directly to the foot or to the shoe insole (Fig. 90.3). Cushioned shoe insoles composed of materials such as Plastazote, Poron, and Spenco may be used to replace the entire existing shoe

FIGURE 90.3 Metatarsal pad attached to shoe insole. The metatarsal pad and bar are designed to redistribute pressure away from metatarsal heads.

insole. Prefabricated insoles with an incorporated metatarsal pad or bar are also available. Custom fabricated foot orthoses may be designed with a depression under the painful metatarsal head areas or with an incorporated metatarsal pad or bar. Although there is limited scientific evidence to support their use, foot orthoses and running shoes with antitorsional features may address abnormal biomechanical forces causing elevated pressure and shearing under the metatarsal heads. Wearing of a shoe with a full-length stiff outsole or “rocker” outsole under the forefoot is advisable [7]. Shoes should have a low heel height, soft insole, and extra depth to accommodate a custom or commercial cushion insole. For patients who stand most of the day because of their occupation, a cushion floor mat can be used. If a capsule or plantar plate tear is suspected (Fig. 90.2), initial immobilization with a prefabricated walking boot may be indicated. Manually reducible dorsal MTP joint contractures may be addressed by applying tape around the base of the toe and securing it to the bottom of the foot [8]. A prefabricated removable toe splint may also be effective for this condition. Mechanically induced metatarsalgia may be treated with oral nonsteroidal anti-inflammatory drugs or a short tapered course of oral glucocorticoids. Metatarsalgia secondary to rheumatoid or other inflammatory arthritis may be addressed by early use of oral disease-modifying antirheumatic drugs [9].

Rehabilitation

If there is posterior lower leg muscle tightness, gastrocnemius or soleus stretching exercises are recommended [10].

Aquatic exercises and bicycle riding are preferable to exercises involving running and jumping. Decreasing stride length while running or fitness walking may also be helpful. Manipulation may be used to stretch out dorsal MTP joint contractures [8]. After the Weil surgical procedure on a lesser metatarsal, vigorous physical therapy to strengthen the toe flexors and to maintain plantar flexion range of motion soon after surgery has been recommended [11,12]. Rehabilitation after hallux valgus surgery, in an effort to avoid “transfer” metatarsalgia, may include strengthening of the peroneus longus muscle, manipulation to improve hallux plantar flexion, plantar and dorsal sliding of the hallux proximal phalanx, oscillating traction of the first MTP joint, and concentric strengthening of the hallux flexor and extensor muscles [13].

Procedures

A diagnostic local anesthetic block of a plantar intermetatarsal nerve may be performed to differentiate between pain originating from an intermetatarsal neuroma and metatarsalgia pain originating from the metatarsal head or MTP joint.

Surgery

Compared with more traditional elevating or shortening distal lesser metatarsal osteotomies, the Weil osteotomy, involving metatarsal head translation with or without elevation, has been reported to achieve good to excellent results [14]. Metatarsalgia in patients with rheumatoid arthritis has traditionally been addressed by excision of the lesser metatarsal heads combined with fusion of the first MTP joint. Recently, with early institution of disease-modifying antirheumatic drugs resulting in sustained low disease activity and remission, MTP joint-sparing surgery has been recommended. However, at this time, there is limited evidence to support this approach [15]. A rupture of the MTP joint plantar plate may be repaired primarily. Hammer toe surgery involving arthrodesis of the proximal interphalangeal joint combined with surgical capsular release and lengthening of the extensor tendons will decrease retrograde plantar pressure on the metatarsal head. A decrease in metatarsalgia has been reported after isolated gastrocnemius recession [16]. Bunionectomy with first metatarsal osteotomy, designed to decrease the angle between the first and second metatarsals, has been shown to decrease painful calluses under the second metatarsal head [17], and a lengthening osteotomy for an iatrogenic short first metatarsal has resulted in decreased metatarsalgia symptoms [18].

Potential Disease Complications

Metatarsalgia pain may result in functional limitation, including antalgic gait, and may lead to falls in the elderly patient population. Rupture of the plantar plate and collateral ligaments may result in MTP joint instability, dorsal toe subluxation, and transverse plane positional toe deformity, including overlapping toes.

Potential Treatment Complications

Intra-articular corticosteroid injections, especially acetate steroids, are generally not recommended in the presence of

lesser MTP joint predislocation syndrome [8]. After corticosteroid injection, MTP joint dislocation [19] and plantar fat pad atrophy have been reported [20]. Other adverse reactions after injection of corticosteroids include skin hypopigmentation at injection site, infection, transient elevated blood glucose concentration, and postinjection flare (pain). Neuroma excision surgery was found to be more technically demanding because of the degree of fibrosis after a series of 20% ethyl alcohol (sclerosing) injections [21], which may also result in adhesive neuritis or “stump” neuroma formation. Topical salicylic acid used to treat painful plantar calluses may injure the skin and lead to open wounds and infection, especially in patients with diabetes. Adverse reactions associated with oral nonsteroidal anti-inflammatory drugs and disease-modifying antirheumatic drugs are listed elsewhere in the text. Shoes with stiff rocker outsoles may cause gait instability and possibly lead to falls, especially in the elderly patient population.

Because of the difficulty in precisely determining the optimal length of a metatarsal when a shortening osteotomy is performed to address metatarsalgia, excessive shortening may result in metatarsalgia of an adjacent metatarsal head and insufficient shortening may lead to some degree of persistent pain [10]. A not uncommon complication of the Weil lesser metatarsal osteotomy is a “floating toe” that does not purchase the floor while standing and walking [10]. Complications of foot orthotic therapy may include mild strain of ligaments, tendons, or muscles; orthotic edge irritation of the skin; and shoe fit difficulty. Improper positioning of a metatarsal pad may result in elevated pressure under the metatarsal head.

Definition

Morton neuroma is not a neoplasm; rather, it is a local, mechanically induced, degenerative enlargement of the third plantar intermetatarsal nerve with associated perineural fibrosis [1] caused by an accumulation of collagenous material within the sheath of Schwann and usually the result of repetitive trauma (Fig. 91.1). As such, it is more accurately defined as an intermetatarsal compression or entrapment

neuropathy [2]. The exact etiology has not been clearly identified or proved conclusively, but the following have been postulated as contributing factors: flatfoot (pes planus); anterior splay foot; high-arch foot (pes cavus); equinus deformity [3]; ill-fitting (tight or high-heeled) shoes; abnormal proximity of neighboring metatarsal heads [4]; and associated forefoot deformities, including hallux abductus, bunion, and lesser hammer toes. Plantar intermetatarsal nerves of the foot are purely sensory at and distal to the level of the metatarsophalangeal (MTP) joints, as they course through a fibro-osseous canal composed of neighboring metatarsal heads and the overlying deep transverse intermetatarsal ligament [5]. Anatomic (cadaver) studies have identified the third intermetatarsal nerve as most commonly receiving proximal branches from both the medial plantar and lateral plantar nerves, each arising from the common posterior tibial nerve. Therefore, anatomically, the third intermetatarsal nerve is usually enlarged to some degree as it develops from proximal trunks of two separate nerve branches. This anatomic configuration may or may not be a causative factor. The classic Morton neuroma occurs in the third intermetatarsal space. Similar nerve compression neuropathies occur, but less commonly, in the second plantar intermetatarsal space (Hauser neuroma) and rarely in the first (Heuter neuroma) and fourth (Iselin neuroma) plantar intermetatarsal spaces [2]. Symptomatic plantar neuromas in neighboring intermetatarsal spaces may occur in the same foot, but uncommonly. They are all treated in a similar fashion.

Symptoms

Morton neuroma may be manifested symptomatically in a variety of ways: localized sharp, lancinating, or burning pain; paresthesias and dysesthesias; numbness and tingling; and toe cramping. Symptoms typically radiate distally, involving the opposing plantar sides of the third and fourth toes, but pain exclusively in the fourth toe is not uncommon. Unilateral presentation is most common, whereas bilateral is less so. Symptoms occur predominantly during weight-bearing activities, but residual non-weight-bearing or nocturnal pain is sometimes present. Not uncommonly, patients may experience symptoms while driving an automobile with the foot held in a slightly dorsiflexed position. A characteristic patient maneuver is to remove the shoe and massage or manipulate the plantar forefoot and MTP joints, producing transient relief of symptoms [6].

FIGURE 91.1 Morton neuroma.

Physical Examination

On inspection, the foot may appear normal or may demonstrate a subtle divergence of the third and fourth toes, usually more pronounced with weight bearing. When it is present, the regional palpable pain is typically plantar. The lateral forefoot squeeze test may mimic a tight shoe, thereby reproducing symptoms. In long-standing cases, hypoesthesia or anesthesia may be noted in the third interdigital web space, distally on the opposing plantar sides of the involved toes (toe tip sensation deficit [7]) or plantar, distal to the third and fourth metatarsal heads. The most diagnostic and reliable clinical maneuver is the Mulder test [8], performed by alternating lateral compression of the forefoot with one hand and dorsal-plantar compression of the involved distal intermetatarsal space with the opposite forefinger and thumb (Fig. 91.2) [6]. A Mulder sign is considered present when symptoms are reproduced and a palpable and sometimes audible click is detected. In general, there are no signs of proximal nerve involvement (e.g., tarsal tunnel syndrome), vasomotor instability, or arterial insufficiency. Predisposing foot types (pes planus or pes cavus) or a tight Achilles tendon (equinus) [3] may be evident on clinical examination. Passive range of motion of the neighboring MTP joints is usually pain free without crepitus. Unilateral antalgic (pain-avoidance) gait may also be observed.

Functional Limitations

Functional limitations include difficulty with walking or running any significant distance and in performing other weight-bearing physical activities as well as the inability to wear dress shoes comfortably (particularly women's high heels).

FIGURE 91.2 Technique to elicit Mulder sign.

Diagnostic Studies

The diagnosis of Morton neuroma is generally made from history and clinical examination. However, other supportive diagnostic studies may be helpful in establishing a diagnosis, especially when surgical intervention is being considered or in the event of failed conservative measures. Ultrasonography is a relatively simple, inexpensive, and helpful diagnostic tool [9,10]. In the evaluation of a primary neuroma, a 5-mm or greater hypoechoic mass, visualized in the coronal (frontal) plane projection between the neighboring metatarsal heads, is considered a positive finding [11,12]. Magnetic resonance imaging, although generally not recommended in the initial evaluation, may also be used, particularly in the presence of equivocal or normal ultrasonographic findings (e.g., small lesions) and when surgical excision is being considered [13–15]. Ultrasonography has a slightly higher sensitivity than magnetic resonance imaging, particularly for neuromas smaller than 5mm in diameter [16]. Both ultrasonography and magnetic resonance imaging are used in the diagnosis of postsurgical recurrent or “stump” neuroma [17–19]. Performance of the Mulder test during sonography is a recently described real-time imaging method, helpful in assessing the dimensions of the nerve as well as the local “dynamics” of the pathologic process (Fig. 91.3) [11]. New high-resolution, high-frequency ultrasound scanning may provide a means of differentiating a neuroma from disease of neighboring soft tissue structures, including the plantar plate and flexor tendons [12]. The neuroma itself is not visible by plain radiographic imaging, but radiographs may be obtained to rule out metatarsal stress fracture, MTP joint disease (degenerative or inflammatory), or contributing neighboring metatarsal head abnormality. Sensory nerve conduction studies can be used, but because of the difficulty in isolating individual nerve trunks or branches, results are not consistently accurate or helpful. Differential latency testing is a new electrodiagnostic approach that is more sensitive, simpler to use, and less painful than conventional electrodiagnostic studies, and it requires no extra equipment. Values above 0.17 millisecond between branches of the common plantar interdigital nerves are consistent with Morton neuroma [20]. Last, a local anesthetic plantar intermetatarsal space injection can be a useful minimally invasive diagnostic maneuver to support the diagnosis.

FIGURE 91.3 Dynamic frontal plane ultrasound image demonstrating plantar displacement of neuroma. The arrows indicate plantar displacement of neuroma beneath metatarsal heads. (From Torriani M, Kattapuram S. *Dynamic sonography of the forefoot: the sonographic Mulder sign*. *AJR Am J Roentgenol* 2003;180:1121-1123.)

Differential Diagnosis

- Metatarsal stress fracture
- Metatarsal head avascular necrosis (Freiberg infraction)
- Metatarsal head osseous neoplasm
- MTP joint soft tissue neoplasm
- MTP joint synovitis
- MTP joint plantar capsulitis
- MTP joint plantar plate rupture or tear
- MTP joint flexor tendinopathy
- Oligoarticular systemic synovitis (e.g., rheumatoid)
- MTP joint arthritis (e.g., degenerative, rheumatoid, post-traumatic)
- Submetatarsal head bursitis
- Localized forefoot ischemia
- Tarsal tunnel syndrome
- Proximal nerve root syndrome (e.g., lumbosacral radiculopathy)
- Peripheral neuritis
- Peripheral neuropathy (e.g., diabetic, alcoholic)
- Rheumatoid nodule

Treatment

Initial

Conservative treatment modalities include shoe gear modifications (e.g., wider toe box), adhesive tape strapping or padding of the foot, and use of foot orthoses. Oral nonsteroidal anti-inflammatory drugs and analgesics may provide some relief from acute symptoms but are not recommended for long-term treatment. Posterior lower leg stretching exercises may be helpful in the presence of gastrocnemius equinus.

Rehabilitation

Physiotherapy modalities, including both iontophoresis and phonophoresis, may help manage acute pain. If symptoms respond to initial conservative “mechanical” measures, such as off-the-shelf arch supports, more individualized therapies such as custom foot orthoses may provide additional

FIGURE 91.4 Technique of injection of a Morton neuroma.

symptomatic relief; these usually require referral to a podiatrist or podorthist for fabrication.

Procedures

Injections with sclerosing agents, such as absolute alcohol [21,22], phenol, and vitamin B₁₂, may be used if initial conservative noninvasive treatments fail. Local anesthetic-corticosteroid injections [15,23], however, are more commonly used and may provide transient (but rarely long-term) relief of symptoms (Fig. 91.4). These injections are limited to no more than three within a 3- to 6-month period because of the potential for plantar fat pad atrophy and MTP joint tendon or ligament rupture. Cryoablation and radiofrequency ablation have been used with mixed results and with a potential for iatrogenic injury to neighboring soft tissue structures.

Surgery

Conservative measures do not always result in symptomatic improvement [24]. The neuroma as well as the distal digital branches and proximal nerve trunk may be too large for their confined anatomic space. In these cases, surgical excision may be necessary [25]. The success rate of surgical excision is approximately 85% to 90%, and surgical revision or reexploration generally carries a poor prognosis [26]. Less traditional surgical techniques include neurolysis, decompression with dorsal nerve transposition [27], transection of the deep transverse intermetatarsal ligament (open or endoscopic), laser treatment (vaporization), distal lesser metatarsal osteotomies, and gastrocnemius recession (in the presence of soft tissue equinus deformity) [28–31].

Potential Disease Complications

Potential disease complications include persistent refractory or intractable nerve pain, reduced mobility, functional limitation, and shoe gear restrictions.

Potential Treatment Complications

Few complications may arise from conservative measures, such as padding, strapping, foot orthoses, and shoe

modifications. On occasion, ipsilateral or contralateral knee, ankle, hip, or even low back pain may occur, but these respond rapidly after discontinuation of treatment. Likewise, there are no significant treatment complications from physiotherapy measures when they are used and applied properly. Long-term use of nonsteroidal anti-inflammatory drugs may lead to gastrointestinal irritation.

Injection therapy with corticosteroids may result in plantar fat pad atrophy and secondary metatarsalgia or MTP joint plantar plate or collateral ligament rupture and subsequent digital deformity. Injection therapy with sclerosing agents may result in perineural irritation, inflammation, and pain. Postsurgical complications include infection, hematoma, vascular compromise, dorsal cutaneous nerve injury, incomplete resection, recurrence [32,33], stump neuroma [34], plantar fat pad atrophy, painful hypertrophic scar formation (especially with plantar incision approach), and reflex sympathetic dystrophy [32,33].

M72.2 Plantar fasciitis

Definition

The plantar fascia is a multilayered fibrous aponeurosis that originates from the medial calcaneal tuberosity and extends distally, becoming wider and thinner and splitting into five bands. Each band then divides into a superficial and deep layer to insert onto the transverse tarsal ligament, flexor sheath, volar plate, and periosteum of the base of the proximal phalanges of the toes [1] (Fig. 92.1). Plantar fasciitis is an overuse injury resulting from repetitive microtears of the plantar fascia at its origin at the tuberosity of the os calcis deep to the distal medial heel pad [2]. It is classically described as a local inflammatory reaction, although recent research has demonstrated the relative absence of inflammatory cells in the injured tissue, suggesting more of a degenerative process; therefore, the terms *tendinosis* and *fasciosis* are advocated [3].

Plantar fasciitis is one of the most common injuries of runners. This condition occurs equally in both sexes in young people; some studies show that a peak incidence may occur in women 40 to 60 years of age [4]. The condition is typically precipitated by a change in the athlete's training program. Such changes may include an increase in intensity

or frequency, a decrease in recovery time, or a change in terrain or running surface. In the nonathlete, an increase in the amount of walking, standing, or stair climbing may also precipitate symptoms. There is a correlation of plantar fasciitis with professions requiring prolonged standing (e.g., police officers and hairdressers).

Risk factors such as pes planus (flat feet), pes cavus with rigid high arches, excessive pronation, obesity, Achilles tendon contracture, and poor footwear (usually a loose heel counter and inadequate arch support) may contribute to the development of this condition. Multiple authors have demonstrated that the successful treatment of plantar fasciitis is not contingent on the surgical removal of a heel spur (calcaneal enthesophyte). Studies have shown that only 50% of patients with plantar heel pain had a heel spur and that only 10% of patients with a heel spur were symptomatic [5].

Symptoms

Patients typically complain of sharp, knife-like pain in the plantar aspect of the heel at the base of the fascial insertion to the calcaneus. Pain is generally worse with standing or during the initial steps on awakening or after prolonged sitting. Patients will often complain of the classic "pain with the first steps in the morning" that eases after being up and about for a while. Pain also typically worsens at the beginning of an exercise session but decreases during exercise. The athlete may describe being able to "run through" the pain. Complaints of numbness, paresthesias, or weakness are atypical for plantar fasciitis; therefore, if these complaints are present, the clinician should suspect an underlying nerve injury.

Physical Examination

Palpation reveals tenderness at the origin of the fascia of the medial calcaneal tubercle, but there may be tenderness along the majority of the fascia. Range of motion often reveals limited great toe dorsiflexion from a tight plantar fascia as well as decreased ankle dorsiflexion from a tight Achilles tendon. Dorsiflexion should be tested with the knee straight (gastrocnemius on stretch) and with the knee bent (gastrocnemius relaxed, soleus on stretch) to better

FIGURE 92.1 A, Plantar view of origin and insertion of plantar fascia. B, Bowstring effect of plantar fascia.

differentiate tightness of the gastrocnemius and soleus muscles. The neurologic examination should reveal normal muscle strength, sensation, and deep tendon reflexes, unless a concomitant neuropathy is present.

Functional Limitations

Depending on the severity of disease, patients may complain of symptoms only when they try to increase running intensity or distance. More severe cases may significantly limit a patient's ability to ambulate during daily activities or climbing stairs. Professions requiring extensive walking or standing (e.g., postal workers, nurses, or waitresses) may

require job modification as well as more aggressive splinting or even casting during the initial phase of treatment.

Diagnostic Testing

Plantar fasciitis is usually a clinical diagnosis. However, radiographs of the foot may be helpful in ruling out other potential causes of heel or foot pain. It is a common misconception that the pain of plantar fasciitis is the direct result of the often (50%) associated anterior calcaneal enthesophyte (heel spur). In fact, a study of 461 asymptomatic patients showed radiographic evidence of heel spurs in 27% of those studied [5].

Electrodiagnostic testing (electromyography) may be helpful in ruling out the possibility of a nerve entrapment.

Ultrasound and magnetic resonance imaging studies may be helpful before surgical intervention is considered; these studies may demonstrate signal changes or swelling within the fascia. Magnetic resonance imaging usually demonstrates edematous involvement of the calcaneal insertion of the plantar aponeurosis, with marked thickening of the central cord of the plantar fascia.

Differential Diagnosis

The differential diagnosis of heel pain [6] includes the following inflammatory, metabolic, degenerative, nerve entrapment, and other conditions.

INFLAMMATORY

Juvenile rheumatoid arthritis
Rheumatoid arthritis
Ankylosing spondylitis
Reiter syndrome
Gout
Diffuse idiopathic skeletal hyperostosis
Psoriatic arthritis

METABOLIC

Migratory osteoporosis
Osteomalacia

DEGENERATIVE

Osteoarthritis
Atrophy of the heel fat pad

NERVE ENTRAPMENT

Tarsal tunnel syndrome
Entrapment of the medial calcaneal branch of the posterior tibial nerve

OTHER

Tumors
Vascular compromise
Infection

in difficult cases. Keeping the foot elevated while sitting or lying down may also help reduce any local inflammation and swelling. Nonsteroidal anti-inflammatory drugs are often used to treat pain and any inflammatory component to the disease process. No studies have specifically examined the effectiveness of nonsteroidal anti-inflammatory drugs alone. More than 90% of patients with plantar fasciitis are cured with conservative measures [6]. Patients are often advised to obtain “stress mats” for prolonged standing on hard floors. Modalities are addressed in the following section.

Rehabilitation

The key elements of rehabilitation include stretching and strength training of not only the lower leg and foot but also the thigh, hip, and back. These include the plantar fascia, gastrocnemius-soleus complex, quadriceps, hamstrings, and hip flexors and extensors [7].

Increased flexibility is achieved through frequent stretching during the day. Each stretch should be held for 30 seconds. It is beneficial to tell patients that muscles need to be reminded to stay elongated; therefore it is better to stretch for 30 seconds 10 times per day than to dedicate an hour once a day to perform stretches. This also helps achieve the patient's compliance.

Strengthening of the foot intrinsic muscles may be achieved by placing a towel on the floor and having the patient crunch up the towel into a ball and then spread it back out by flexing and extending the toes. Alternative aerobic exercises or “cross-training” should be prescribed to minimize the effects of deconditioning. This can generally be achieved with running or swimming in the pool as well as by low-resistance cycling.

Therapeutic modalities include local ultrasound, iontophoresis, and phonophoresis. Although there is little evidence in the literature to suggest that these modalities hasten the resolution of the underlying problem, they may be helpful in controlling the patient's pain symptoms, thus allowing better participation in a rehabilitation exercise program. As symptoms resolve and the patient has achieved good flexibility as well as normal peroneal and posterior tibial muscle strength, a gradual return to sport is attempted. An appropriate return to running program should be established by the provider together with the patient. This can generally be achieved by having the patient start at half of the time or distance and intensity that he or she was running before the injury, divided into equal walk and jog intervals. For example, if a patient was running up to 30 minutes before the injury, an appropriate return to running schedule might be as follows: Alternate 4 minutes of walking with 1 minute of jogging for a total of 15 minutes. Increase by 5 minutes every week until 30 minutes is reached. Next, decrease the walk time intervals to 3 minutes each and increase the jog time intervals to 2 minutes. Each week, diminish walk time intervals by 1 minute and add 1 minute to the jog interval. Walk-jog sessions should be performed three times per week, allowing 24 hours of rest between workouts. If at any time the symptoms begin to reappear, return to the walk-jog intensity of the previous week for another week until advancing again. It is generally recommended to start on level surfaces before introducing hills. Patients must be cautioned to not “overdo it” and to stay within a structured rehabilitation program because reinjury is common.

Treatment

Initial

As with most overuse injuries, initial treatment should follow the PRICE principles: *protection, rest, ice, compression, elevation, medications, and modalities*. Protection and rest usually involve “relative rest”; the patient avoids aggravating activities while maintaining cardiovascular and muscle fitness by participating in low-impact activities such as swimming, bicycling, and weightlifting. Ice massage to the plantar fascia can easily be performed by the patient at home. Have the patient put a Styrofoam or paper cup full of water into the freezer. Once the water becomes ice, the patient may massage the block of ice along the origin of the plantar fascia for approximately 10 to 15 minutes. Icing is most helpful after activities or at the end of the day. Compression by way of taping the sole of the foot or applying an elastic wrap around the foot may offer comfort to the patient, as may soft gel heel cups, which may be placed in the patient's shoes. Casting in a neutral position helps

Management of excessive foot pronation is essential to correction of a common contributing biomechanical factor [8]. This may be achieved simply by stretching the Achilles tendon; however, a change in footwear is often indicated. Numerous running shoes are on the market, and a good running shoe store with a knowledgeable staff may be helpful in finding the appropriate shoe for a particular type of foot. Essential components include a good heel counter and reasonable midfoot flexibility. Patients who demonstrate excessive hindfoot valgus and forefoot varus deformities typically benefit from custom-made orthotic devices that incorporate medial-side wedging. Patients should be cautioned about wearing high-heeled shoes, especially those with hard soles, as this will increase the forces across the plantar fascia as well as promote Achilles tendon shortening.

Procedures

Posterior night splinting may prove effective in resistant cases. Off-the-shelf devices are available, or fabrication of a posterior splint is simple with use of fiberglass casting tape. The patient's foot should be splinted in maximum dorsiflexion to allow maximum lengthening of the plantar fascia and to prevent the stiffening and contraction that normally occur during sleep. The splint should be applied every evening and worn throughout the night for 2 to 3 weeks. If the patient finds wearing the splints uncomfortable at first, a gradual "break-in" period may be necessary, with the goal of wearing the splints throughout the night in 1 to 2 weeks. A study demonstrated that about 90% of patients with refractory symptoms improved after only 1 month of treatment [9].

Corticosteroid injections can often be avoided if an effective treatment plan is adhered to. In refractory cases, however, a local steroid injection may allow the patient to be more compliant with the established rehabilitation program [10]. We prefer to inject a combination of 10 to 20 mg of triamcinolone (Kenalog) and 4 mL of 1% lidocaine with a 25-gauge, 1½-inch needle. A medial approach is used as it is generally better tolerated by the patient. The needle is aimed toward the medial tubercle of the calcaneus or most tender point, ensuring that the injection is above the fat pad to avoid potential fat pad atrophy (Fig. 92.2). Ultrasound guidance is now often used for more accurate injection with hopes of minimizing this complication (Fig. 92.3). Ultrasound-guided injection of dexamethasone sodium phosphate was shown to be safe and to provide some short-term benefit at 4 weeks [11].

Extracorporeal shock wave therapy is a treatment that generates shock waves by electrohydraulic, piezoelectric, or electromagnetic methods. A meta-analysis evaluated 20 published studies that clinically supported this treatment method as effective for plantar fasciitis. Two mechanisms are hypothesized for this treatment's efficacy. First, it is thought that the transmitted waves have an effect on pain receptor physiology. Second, the transmitted waves initiate fascial tissue healing through microtrauma and a subsequent healing response by the release of molecular agents and growth factors. An advantage to this treatment method is immediate weight bearing and return to most activities in 1 to 2 weeks [12].

FIGURE 92.2 Proper approach for injection of plantar fascia.

FIGURE 92.3 Ultrasound image (long-axis view) of the plantar fascia (arrows). From superior to inferior: subcutaneous fat, plantar fascia, flexor digitorum brevis (FDB) muscle.

Autologous blood injections have shown promise for recalcitrant plantar fasciitis. Martin [13] injected 1 mL of lidocaine and 2 mL of autologous blood where the plantar fascia was most tender. This treatment has been shown to decrease pain severity and to increase functional activity.

Babcock and Foster [14] investigated the effect of botulinum toxin in refractory plantar fasciitis. This randomized, double-blind, placebo-controlled study yielded significant improvements in pain relief and overall foot function at both 3 and 8 weeks after treatment.

Surgery

Surgery may be indicated in patients with significant disability and persistent pain when conservative measures have failed. The two most common surgical options are open and endoscopic release. Overall successful outcomes range from

48% to 90% [15]. A successful outcome could be expected for most patients who are treated for recalcitrant plantar fasciitis.

Potential Disease Complications

Patients who continue untreated and run through their pain typically have progressive symptoms, which begin to interfere with their activities of daily living and may lead to irreversible fascial degeneration and damage.

Potential Treatment Complications

Although corticosteroid injections may help selected patients to participate in a more effective rehabilitation program, this procedure should be performed with reservation because it may lead to heel fat pad atrophy or even plantar fascia rupture [16]. For this reason, it may be helpful to apply a walking splint or cast for several days after an injection.

Because of the risk of gastrointestinal bleeding, long-term use of nonsteroidal anti-inflammatory drugs should be avoided, and they should be used with caution in elderly patients or those with a history of gastrointestinal or bleeding disorders. The use of nonsteroidal anti-inflammatory drugs is contraindicated in patients with a known hypersensitivity to them.

Surgery, whether endoscopic or open, is associated with several risks (infection, complete rupture). Postoperative rehabilitation may require several weeks of limited or no weight bearing on the affected extremity.

726.72 Tibialis tendinitis (posterior)

ICD-10 Codes

M76.821 Posterior tibial tendinitis, right leg
M76.822 Posterior tibial tendinitis, left leg
M76.829 Posterior tibial tendinitis, unspecified leg

Definition

The tibialis posterior muscle, originating from the proximal tibia and fibula, passes distally with a broad insertion on the plantar aspect of the navicular, cuneiform, cuboid, and metatarsal bases and normally functions to invert the subtalar joint and to adduct the forefoot. Its principal antagonist is the peroneus brevis, which normally everts the subtalar joint and abducts the forefoot. Posterior tibial tendon dysfunction is a condition, as its name suggests, that is characterized by the loss of function of the posterior tibial tendon. This disabling problem may be caused by trauma, degeneration, or inflammatory arthritides and is most commonly seen in the sixth to seventh decades of life [2]. These pathologic processes can lead to reduction of effective excursion of the tendon or even rupture, resulting in progressive loss of the medial arch, midfoot abduction, and forefoot pronation. Posterior tibial tendon dysfunction is the most common cause of acquired flatfoot in the adult. Usually,

posterior tibial tendon dysfunction is a chronic, progressive process, but spontaneous rupture can occur in patients receiving long-term steroid therapy or after trauma.

In regard to pathophysiology, the posterior tibial tendon functions in concert with the gastrocnemius-soleus complex to stabilize the hindfoot. The longitudinal arch is stabilized primarily by bone articulations and ligamentous structures (spring ligament, talocalcaneal interosseous ligament, superficial deltoid) and only secondarily supported by the posterior tibial tendon. The initial pathologic change is typically tendinosis of the posterior tibial tendon with maintenance of the longitudinal arch. As the tendon becomes less efficient, more stress is placed on the medial ligamentous structures, which attenuate, leading to progressive loss of the arch and abduction of the midfoot [3]. The posterior tibial tendon begins to atrophy while the flexor digitorum longus hypertrophies in an attempt to compensate [4]. Next, the calcaneus will drift into a valgus malalignment, changing the lever arm of the Achilles and causing a heel cord contracture. Finally, the peroneus brevis becomes an unopposed antagonist and exacerbates the deformity.

Symptoms

Patients, most commonly middle-aged women, primarily complain of pain on the inner or medial aspect of the ankle and the hindfoot. As the insufficiency progresses, pronation increases, leading to pain over the dorsolateral aspect of the midfoot [5,6]. Typically, this results in a gradual loss of the arch associated with a corresponding increase in pain.

Rarely, there is a history of a rapid collapse from rupture after an acute injury [7,8]. There have been only six reported cases in the literature of athletes (basketball players and runners) younger than 30 years with acute posterior tibial tendon ruptures [9–12].

Physical Examination

The physical examination reveals swelling confined to the area around the medial malleolus. In general, there is tenderness along the course of the tendon, and there may be exquisite tenderness just distal to the medial malleolus where the tendon most commonly tears [13,14].

Assessment of the lower extremity in the weight-bearing position best demonstrates the essential elements

of the deformity: valgus hindfoot (calcaneovalgus), midfoot abduction, and forefoot pronation. This complex deformity clinically demonstrates a “too many toes” sign, that is, when the feet are viewed from behind, there appear to be more toes on the affected side than on the unaffected side. The severity of the patient’s presentation depends on the chronicity of the insufficiency and the magnitude of the tendon dysfunction. The medial longitudinal arch of the foot may be entirely lost.

The anterior tibial tendon may become more visible than on the normal side as the patient, subconsciously, tries to regain the arch. Patients may have difficulty walking on their tiptoes or have difficulty performing a one-sided toe-stand while holding on to the clinician’s hands. The heel fails to invert into a varus position. Asking the patient to invert the plantar-flexed foot against resistance can be overcome by the clinician’s hand. Assessment of the patient on the couch reveals altered posture of the foot due to the unopposed action of the peroneus brevis. A callosity can be seen in the region of the medial plantar aspect of the midfoot.

Posterior tibial tendon dysfunction can be classified in three stages that are correlated to the treatment. Stage I is a tenosynovitis, normal tendon function, and no deformity. Stage II is a spectrum of disease that includes tendinosis but also posterior tibial tendon dysfunction and weakness. Loss of the medial arch and progressive valgus of the heel with mild lateral impingement can be seen. Early in stage II, the patient may be able to perform a single heel raise, but as this stage progresses, this function is lost. Most important, the flexibility of the foot is maintained with nearly normal subtalar, midtarsal, and forefoot motion. This continuum of disease may progress to stage III as the deformity becomes more rigid and subtalar degeneration occurs with subsequent decreased motion. Lateral tenderness is present because of impingement of the distal fibula on the calcaneus. A heel cord contracture is also apparent in most cases.

Functional Limitations

Patients may experience fatigue after only limited activity as their gait mechanics change with progressive pronation. They may have difficulty finding well-fitting footwear. Pain is usually the greatest complaint and also limits walking and sports-related activities [15].

Diagnostic Studies

Weight-bearing foot and ankle radiographs are usually helpful, depending on the severity of the clinical findings. In the earlier stages of tenosynovitis, the radiographs are usually normal, even if there is some mild clinical flattening of the medial longitudinal arch. As the problem progresses, radiographic changes occur (Figs. 93.1 and 93.2). These include, on the anteroposterior view, uncovering of the head of the talus (as the navicular moves laterally) and increase of the angle between the bodies of the talus and the calcaneus; on the lateral view, plantar flexion of the talus, collapse of the navicular-cuneiform joint, and overlapping of the four medial metatarsals are noted.

Ultrasonography has been used in the past to visualize the posterior tibial tendon both statically and dynamically and to demonstrate the tendon’s excursion. Currently, the “gold standard” is magnetic resonance imaging to evaluate

FIGURE 93.1 Anteroposterior view of the foot. Stage II with uncovering of the talar head.

FIGURE 93.2 Lateral view of the foot. Stage II with decreased calcaneal height and talar–first metatarsal angle.

the continuity of the tendon. This provides a reasonably accurate view of the degree of inflammation and synovial fluid present within the tendon sheath as well as determines whether a tear of the tendon is present.

Differential Diagnosis

- Tarsal coalition–spastic flatfoot
- Degenerative arthritic deformity
- Idiopathic flexible pes planus
- Neuropathic arthropathy (e.g., secondary to diabetes mellitus)
- Midtarsal collapse
- Congenital pes planus
- Lisfranc dislocation
- Generalized dysplasia (ligamentous laxity)

Treatment

Initial

The first line of management, in stage I of posterior tibial tendon insufficiency, is with orthoses. Custom orthotic devices with longitudinal arch support and medial heel lift shoe inserts, University of California Biomechanics Laboratory (UCBL) inserts, rigid ankle-foot orthoses, and even double upright braces may be necessary. Unfortunately, there is no proof that any orthotic device can halt progression of the disorder, and if the deformity is less flexible, orthoses may be poorly tolerated. On occasion, a short leg cast is applied for 4 to 6 weeks for rest. Patients who have enough pain to require a boot or cast are also given a prescription for a wheelchair and walker. They are advised to be minimally weight bearing for at least 2 weeks. If the pain improves, they may gradually progress weight bearing in the boot. When they are pain free with weight bearing in the boot, they progress to a cushioned lace-up shoe and arch support. Pain should be the guide as to how fast patients may progress weight bearing. Anti-inflammatory medication may help alleviate some of the pain from the tenosynovitis. In obese individuals, weight loss can be critical.

Rehabilitation

Once the acute inflammation has settled, an exercise program may be started to strengthen the posterior tibial tendon. This can include active-resisted exercises with elastic materials (such as Cliniband or Thera-Band) and an exercise akin to trying to "pick up carpet with the sole of the foot" or "grasping a towel." Further methods include muscle stretching and strengthening techniques, particularly aimed at the Achilles tendon. Proprioceptive drills to improve balance on the wobble board and gait reeducation are also important.

Postoperative rehabilitation can include therapy for range of motion exercises after tenosynovectomy and most certainly after tendon transfer surgery to strengthen the muscle-tendon complex. After a subtalar or triple arthrodesis, the patient will have had a lengthy period of cast immobilization, and therefore gait reeducation can be beneficial.

Procedures

Injection of local anesthetic and steroid into the tendon sheath is a contentious subject and is not recommended because of the possibility of tendon rupture.

Surgery

Different surgical procedures are recommended, depending on the stage of the disease. Continuing pain and failure of nonoperative management of tenosynovitis (stage I) are the main indications for tenosynovectomy to remove all the inflamed synovium. This is followed by a period of cast immobilization. Repair of incomplete tears of the tendon may also be indicated and can be augmented by tendon transfers.

Complete tendon disruption, in the absence of bone collapse (stage II), can be treated with tendon transfers, combining a flexor digitorum longus transfer with a medial sliding calcaneal osteotomy. Subtalar or triple arthrodesis may be indicated for patients with progressively worsening deformity and lateral hindfoot pain (stage III) [16,17].

Postoperative gait analysis of patients after tendon transfer and osteotomy shows improvements compared with the preoperative analysis in ankle push-off power, step length, velocity, and cadence [18]. Long-term satisfaction with this procedure is high: 97% improvement in pain, 94% improvement in function, and 84% ability to wear shoes without modification or orthotic device [19].

Potential Disease Complications

Posterior tibial dysfunction can result in progressive pain and deformity, restriction of mobility, valgus deformity of the knee, and medial longitudinal arch ulceration as the medial midfoot collapses, causing increased pressure with weight bearing in this region.

Potential Treatment Complications

Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Steroid injection can cause tendon rupture. Complications of surgery include wound infection (in an area that can be notoriously slow to heal) and nonunion or failure of fusion in attempted arthrodesis.

ICD-10 Codes

G57.50 Tarsal tunnel syndrome, unspecified lower limb
G57.51 Tarsal tunnel syndrome, right lower limb
G57.52 Tarsal tunnel syndrome, left lower limb

Definition

Tarsal tunnel syndrome can be described as a constellation of signs and symptoms caused by entrapment or compression of the tibial nerve or any of its branches within the tarsal tunnel, the region beneath the flexor retinaculum on the medial aspect of the ankle (Fig. 94.1). The tibial nerve branches that may be involved deep to the tarsal tunnel include the medial plantar nerve, lateral plantar nerve, Baxter nerve (also known as the first branch of the lateral plantar nerve or inferior calcaneal nerve), and medial calcaneal nerve [1]. Anatomically, the tarsal tunnel is a fibro-osseous structure that begins just posterior to the medial malleolus; the roof is the flexor retinaculum (also called the lacinate ligament), and the floor is formed by the tendons of the posterior tibialis, flexor digitorum longus, and flexor hallucis longus muscles. The tibial nerve usually divides into three

branches at the level of the ankle: the medial plantar nerve, the lateral plantar nerve, and the medial calcaneal nerve. However, Baxter nerve (i.e., first branch of the lateral plantar nerve) usually branches from the lateral plantar nerve (but can branch off the tibial nerve) just distal to the origin of the medial calcaneal nerve at the level of the tarsal tunnel [2,3]. Baxter nerve then traverses laterally across the anterior aspect of the heel and terminates with motor branches to the abductor digiti quinti (or minimi) pedis muscle [2]. It is likely that tarsal tunnel syndrome occurs infrequently compared with other well-known focal entrapment neuropathies, such as carpal tunnel syndrome, ulnar neuropathy at the elbow, and peroneal (fibular) neuropathy at the knee. In fact, in a retrospective review of isolated tibial neuropathies in the foot, the incidence of Baxter neuropathy (17%) was much greater than that of tarsal tunnel syndrome (5%) [4].

There are generally considered to be five basic categories that account for the etiology of tarsal tunnel syndrome: trauma and post-traumatic changes, mass or space-occupying lesions causing compression, systemic diseases, biomechanical causes related to joint structure or deformity, and idiopathic causes. In addition, the underlying pathophysiologic mechanism of tarsal tunnel syndrome remains elusive; a portion of the literature supports the process of demyelination, whereas other sources implicate axonal degeneration as the primary process [5,6]. It is thought that the tibial nerve may be entrapped proximally within the tarsal tunnel, or one of its branches (e.g., the medial plantar nerve) may be entrapped distally in its own calcaneal chamber [1]. Entrapment of the first branch of the lateral plantar nerve (i.e., Baxter nerve) has also been described as a cause of heel pain [7–10]. Therefore in a case of clinically suspected tarsal tunnel syndrome, the tibial nerve and its major terminal branches (including the medial plantar nerve, lateral plantar nerve, and Baxter nerve) should be thoroughly evaluated [4].

In the current literature, there is no mention of an age or gender preference in patients with tarsal tunnel syndrome. One possible explanation for this is the relatively low incidence and various causes of tarsal tunnel syndrome.

Symptoms

The patient usually presents with pain or paresthesias along with numbness over the sole of the foot [1,11]. Pain is

FIGURE 94.1 Medial aspect of the right foot. The tibial nerve traverses through the tarsal tunnel and then branches into the medial calcaneal nerve, medial plantar and lateral plantar nerves, and first branch of the lateral plantar nerve (i.e., Baxter nerve). Note that the medial calcaneal nerve branches may pierce the flexor retinaculum as they course toward the medial plantar aspect of the heel.

typically described as burning or a dull ache, but it may also be expressed as throbbing, cramping, or even tightness, and pain may extend proximally to the medial calf. Symptoms are often exacerbated by prolonged standing or walking and may be worse at night but may not be well localized. However, if the distribution of sensory disturbance is limited to a particular region of the foot, these symptoms could correspond to a specific tibial nerve branch that is involved (e.g., medial sole of foot due to medial plantar nerve involvement). Obvious weakness of the intrinsic foot muscles is an uncommon patient complaint and may be manifested only if the resulting foot deformity is grossly noticeable or so severe that it causes an unstable gait pattern. Patients with tarsal tunnel syndrome generally present with unilateral symptoms.

Physical Examination

Sensory examination of a patient with tarsal tunnel syndrome should reveal decreased light touch or pinprick over the plantar aspect of the foot corresponding to the distribution of one or all of the tibial nerve branches involved (Fig. 94.2). Motor examination of the intrinsic foot muscles is challenging because it is often difficult for patients to selectively activate these muscles. However, one may be able to appreciate muscle atrophy of the involved foot because its appearance may be asymmetric compared with the other foot [1]. A patient with tarsal tunnel syndrome often has a Tinel sign over the tibial nerve or one of its branches in the tarsal tunnel (Fig. 94.3). On occasion, percussion over the

tibial nerve at the ankle will elicit pain extending proximally along the course of the tibial nerve; this sign is called the Valleix phenomenon. There may also be palpable tenderness over the tibial nerve in the tarsal tunnel. Two other provocative maneuvers that may reproduce symptoms in the foot or ankle are extension of the great toe and sustained

FIGURE 94.2 Cutaneous innervation of the sole of the foot.

FIGURE 94.3 Tinel sign over the tibial nerve posterior to the medial malleolus.

passive eversion of the ankle [1]. Muscle stretch reflexes in the lower extremity (including patellar, medial hamstring, and Achilles) should be normal and symmetric compared with the unaffected side. Peripheral pulses (posterior tibial and dorsalis pedis) are usually palpable and unremarkable. If the biomechanical configuration of the foot is altered severely enough, gait deviations can be observed.

Functional Limitations

Impaired balance or a perception of instability due to diminished sensation or pain on the sole of the foot may be the only functional impairment that is reported by the patient. As a consequence, limited walking tolerance, reduced walking distance, stumbling, or falls may be reported by the patient.

Diagnostic Studies

Electrodiagnostic testing should be performed for any patient with clinically suspected tarsal tunnel syndrome; this is the only diagnostic study that evaluates the electrophysiologic function of the tibial nerve and its major terminal branches. Both needle electromyography and nerve conduction studies (i.e., motor, sensory, or mixed nerve studies) should be done. Furthermore, it is imperative that the tibial nerve be thoroughly evaluated from an electrophysiologic standpoint because either the tibial nerve or one or more of its terminal branches may be involved in clinically suspected tarsal tunnel syndrome [4,10]. A magnetic resonance imaging study may be useful in detecting a space-occupying mass that is impinging on or compressing the tibial nerve within the tarsal tunnel [12]. The magnetic resonance imaging study can also provide a “road map” for surgical exploration of the tarsal tunnel and then direct the procedure toward suitable anatomic decompression of the nerve [13]. The literature indicates that

ultrasonography can be a complementary diagnostic imaging technique for cases of suspected tarsal tunnel syndrome by identifying space-occupying masses such as ganglia [14]. Plain radiographs and a bone scan may be needed to rule out a possible fracture or other bone lesion.

Differential Diagnosis

- Plantar fasciitis
- Peripheral neuropathy
- Sciatic neuropathy
- Lumbosacral plexopathy
- Posterior tibialis dysfunction
- Lumbosacral radiculopathy

Treatment

Initial

Conservative measures can be effective in the majority of tarsal tunnel syndrome cases, and therefore most patients should be given an adequate trial, which is generally at least 3 to 6 months. Initial management usually includes nonsteroidal anti-inflammatory drugs and possibly a neuropathic pain medication (such as gabapentin). If there is a biomechanical foot condition that can be corrected or supported, the patient could benefit from a medial arch support (for a pronated foot) or a foot orthosis (for hindfoot valgus) [7]. In some patients, a short leg walking cast or boot brace can provide symptomatic relief [15].

Rehabilitation

Physical therapy can be useful in certain cases, most typically with modalities such as iontophoresis to reduce symptoms of inflammation, deep massage to mobilize scar tissue, desensitization, and various exercises—such as stretching exercises of the toe flexors, both active and passive, and of the ankle muscle groups (i.e., dorsiflexors, plantar flexors, invertors and evertors) along with specific nerve mobilization exercises [16]. Strengthening exercises for the toe flexors and extensors and for the ankle muscle groups may also be prescribed for distinct motor deficits with a goal of equalizing any muscle imbalance. In addition, gait training along with balance training, both static and dynamic, may be necessary. The patient may require extra-depth shoes to accommodate a medial arch support or a custom-made foot orthosis. Therefore an orthotist or pedorthist may need to manufacture these custom-made orthotics or footwear.

Procedures

For diagnostic and therapeutic purposes, a local anesthetic-steroid injection into the tarsal tunnel can give relatively immediate relief of local swelling and inflammation surrounding the tibial nerve.

Surgery

Surgical management consists of release of the flexor retinaculum and possibly exploration for a mass or space-occupying

lesion and neurolysis of the tibial nerve, depending on the surgeon [1]. In addition, some surgeons advocate release of the superficial and deep fascia of the abductor hallucis to more completely decompress the tibial nerve and its terminal branches. The success rate (good to excellent outcome) for tarsal tunnel release is variable and reported to be 44% to 78%, depending on the study [13]. Endoscopic release of the tarsal tunnel may be a potential surgical option in some cases [13,17].

Potential Disease Complications

Several potential disease complications may be a consequence of tarsal tunnel syndrome. Skin breakdown, including ulcerations, can occur over the plantar aspect of the foot as a result of impaired sensation. An altered gait pattern may develop with decreased balance or a “feeling of unsteadiness” because of impaired sensation, particularly with respect to proprioception and light touch or pressure in the foot, or because the biomechanical configuration of the foot is distorted. Low back pain or lower extremity joint pain (probably hip or knee) may arise as a consequence of the gait deviation.

Potential Treatment Complications

Nonsteroidal anti-inflammatory drugs may cause, most commonly, gastric or renal complications. Skin breakdown can develop over the foot or ankle from a poorly fitting foot orthosis. Tendon rupture may occur after steroid injection into the incorrect location (e.g., flexor tendon sheath). In addition, the symptoms of pain, numbness, and paresthesias in the foot can be exacerbated after a local anesthetic-steroid injection or after surgical decompression of the tarsal tunnel.

Chronic leptomeningitis

ICD-9 Code

322.9 Arachnoiditis

ICD-10 Code

G03.9 Arachnoiditis (spinal) NOS

Definition

The meninges are a system of three protective membranes that surround the central nervous system and consist of the pia mater, arachnoid mater, and dura mater layers. Arachnoiditis is the development of chronic inflammation and progressive fibrosis of the arachnoid and pia layers of the meninges. It can occur subsequent to a variety of conditions, although it is most commonly a sequela of spinal surgery or the result of intrathecal injection of radiographic dyes and chemicals with neurotoxic preservatives [1]. Some of the etiologic factors linked to the development of arachnoiditis are listed in Table 95.1. Because arachnoiditis is rare, specific incidence and prevalence are uncertain.

When microtrauma to the vasculature of the arachnoid membrane and pia mater occurs, it can impair the normal mechanisms for control of excessive meningeal fibrosis [1]. This may result in the deposition of fibrous collagen bands in the arachnoid-pia membranes and cause the nerve roots to adhere to each other as well as to the dural sac. The pathophysiologic mechanism of arachnoiditis involves a progression from root inflammation (radiculitis) to root adherence (fibrosis). In severe cases, the arachnoid fibrosis can cause compressive root ischemia, and progressive neurologic deficits may ensue [2]. When this condition occurs in the meninges of the cervical and thoracic regions, the spinal cord can become enmeshed and constricted as well. Pain is the

result of dural adherence with nerve root traction and nerve ischemia. Typically, arachnoiditis develops slowly during the period of months after the initial insult, although it may continue to develop for years, resulting in worsening pain and paresthesias or progressive neurologic injury [1].

Symptoms

The symptoms associated with arachnoiditis are heterogeneous and often difficult to distinguish from other disease processes, such as radiculopathy, spinal stenosis, cauda equina syndrome, and neuropathies. Also, because arachnoiditis is often acquired iatrogenically during the course of evaluation and treatment of spinal disorders, patients often have concomitant symptoms of mechanical back pain or myofascial pain in addition to the arachnoiditis symptom complex.

Patients with arachnoiditis principally report burning pain or paresthesias. However, these symptoms often do not follow typical radicular patterns. Pain is usually constant but exacerbated by movement. Some patients experience secondary muscle spasms. Weakness and muscle atrophy may also occur, and bowel or bladder sphincter dysfunction is not uncommon. Onset is insidious, and symptoms may first be manifested years after the inciting event [3]. Symptoms can range from mild (such as slight tingling of the extremities) to severe (such as excruciating pain with progressive neurologic deterioration). The condition may also be asymptomatic and discovered only incidentally on magnetic resonance imaging (MRI).

Physical Examination

Neurologic examination typically reveals a patchy distribution of lower motor neuron deficits. Examination findings may include loss of reflexes, muscle weakness, muscle atrophy, anesthesia, gait instability, and reduced rectal tone [2]. Less commonly, arachnoiditis may involve the spinal cord; in these instances, upper motor neuron findings (hyperreflexia, spasticity, presence of Babinski response) can be found on examination.

A complete neurologic examination should be performed at the time of initial diagnosis. In the event that symptoms worsen, this examination may then be used as a benchmark to ascertain whether neurologic deterioration is occurring. In the setting of progressive neurologic decline, it is incumbent on the treating physician to rule out other pathologic processes (such as a new disc herniation) before neurologic

deterioration is attributed solely to progressive arachnoid fibrosis.

Functional Limitations

Patients with arachnoiditis may exhibit a variety of functional limitations, the degree of which corresponds to the extent of the neurologic impairments and the severity of the pain. Gait instability, reduced ambulatory capacity, and impairment in activities of daily living are not uncommon. As time goes by, patients tend to suffer secondary effects of immobilization and deconditioning, causing further functional impairment. The severe pain and impaired mobility tend to isolate patients socially and to limit their ability to work. Because the pain associated with arachnoiditis is usually present even at rest, sedentary work or light duty does not always improve a patient's symptoms enough to facilitate employment despite activity restrictions.

Diagnostic Studies

Presently, the diagnosis of arachnoiditis is most often made through the use of MRI. Historically, myelography was used routinely for diagnosis of arachnoiditis; characteristic findings included the observance of prominent nerve roots as well as various patterns of filling defects. The advent of computed tomography and MRI has made diagnosis easier.

MRI is preferred to computed tomographic myelography because of its noninvasive nature. Typical findings include adherent roots located centrally in the thecal sac (considered mild arachnoiditis), an "empty sac" (where roots are adherent to the wall of the thecal sac), and a mass of soft tissue replacing the subarachnoid space (severe disease) [4]. These findings are well seen on T2-weighted axial images (Figs. 95.1 and 95.2). Although the administration of contrast material

FIGURE 95.1 Normal MRI appearance of lumbar nerve roots on T2-weighted axial sequences.

FIGURE 95.2 Lumbar MRI demonstrating the characteristic nerve root clumping indicative of arachnoiditis.

with MRI may help rule out other diseases in the differential diagnosis, such as tumors and infection, contrast enhancement is not necessary to visualize the characteristic appearance of arachnoiditis [5].

The diagnosis can also be made by computed tomographic myelography; even myelography with conventional radiography may be used if spinal instrumentation from prior fusion surgery creates too much artifact on MRI and computed tomography. The water-soluble myelographic contrast media used today (such as iohexol) are much safer than the prior oil-based media (Pantopaque), and serious adverse reactions involving the central nervous system are extremely rare (<0.1%) [6]. There have not been any documented cases of adhesive arachnoiditis with the use of iohexol myelography [6].

Differential Diagnosis

Spondylosis
Radiculopathy
Cauda equina syndrome
Neuropathy, plexopathy
Neurogenic claudication
Spinal tumors
Spinal infections
Postsurgical epidural fibrosis
Epidural hematoma
Meningitis

Treatment

Initial

The treatment of arachnoiditis is palliative, and medications are often used for this purpose. Antidepressant or anticonvulsant analgesics are considered the mainstay of medical management, although other classes of medications may provide benefit as well. Many antidepressants and anticonvulsants have been used for years off-label for the treatment of neuropathic pain with reasonable efficacy. The tricyclic antidepressants (such as amitriptyline) are the most common. The U.S. Food and Drug Administration has more recently approved several newer medications for use in specific neuropathic pain syndromes: duloxetine and pregabalin for diabetic neuropathy, and gabapentin and pregabalin for postherpetic neuralgia. These medications are often tried in patients with arachnoiditis with varying efficacy. Antidepressant and anticonvulsant analgesics are typically started at relatively low doses and titrated upward as tolerated. The precise starting dose and eventual maximal dose usually depend on how well the medication's side effects are tolerated. Some examples of dosing regimens are listed in Table 95.2. For most of these medications, it often takes a few weeks at any given dose for optimal analgesic effect to be reached.

Anti-inflammatory medications (nonsteroidal anti-inflammatory drugs) are commonly used as well with modest efficacy. This is probably because of the frequent occurrence of back pain in these patients. Often, patients with arachnoiditis have concomitant lumbar disc degeneration or osteoarthritis of the facet joints that may respond

in part to anti-inflammatory medications. Likewise, patients with back pain may benefit from trials of muscle relaxants or more potent inhibitors of muscle contractions (antispasticity agents), such as baclofen and tizanidine. Baclofen has also been used off-label for treatment of neuropathic pain.

Opiates are often prescribed with varying degrees of success. In general, neuropathic pain seems to be less responsive to opiates. Some advocate the use of methadone because of its *N*-methyl-D-aspartate (NMDA) receptor antagonist activity, which may make it more effective for neuropathic pain syndromes. One of the chief limitations of opiates is the tendency for development of tolerance, requiring dose escalation.

Rehabilitation

Rehabilitation interventions can be divided into modalities for pain management and therapeutic exercise to improve pain as well as to aid function. Modalities such as heat application (superficial and deep) and ice application are most effective for treatment of the associated mechanical back pain and myofascial pain that often accompany arachnoiditis. Contrast baths can be used for distal extremity pain and can be helpful when the patient exhibits signs of peripheral sympathetic dysfunction. Electrical stimulation is primarily used to treat neuropathic pain, but it may also improve associated musculoskeletal and myofascial pain. Transcutaneous electrical nerve stimulation and percutaneous electrical nerve stimulation can be applied at the paraspinal level or along the course of a peripheral nerve to help attenuate neuropathic pain.

Unfortunately, exercise typically offers the patient very little as a direct means of symptom improvement for severe neuropathic pain; yet exercise is still an important part of treatment. As previously mentioned, patients with arachnoiditis may suffer from other musculoskeletal pain, and therapeutic exercise (such as stretching, strength training, and aerobic exercise) often improves these associated disorders in this subset of patients as well as in those with chronic pain [7,8]. Patients with intractable pain often avoid activity because of increased pain or fear of pain provocation. As such, they often become deconditioned and benefit from gentle progressive exercise regimens. Aquatic therapy is generally well tolerated and can be used as a method to improve many of the manifestations of deconditioning and prolonged immobility, such as to improve joint motion, flexibility, aerobic capacity, and muscle strength.

Table 95.2 Examples of Dosing Regimens for Anticonvulsant and Antidepressant Analgesics

Medication	Starting Dose	Dose Increase and Interval	Maximal Dose
Tricyclic antidepressants	10-25 mg at night	10-25 mg per week	150 mg/day
Duloxetine	20-30 mg/day	20-30 mg per week	60 mg/day
Gabapentin	100-300 mg bid-tid	100-300 mg per week	1800-3600 mg/day
Pregabalin	50-75 mg bid-tid	50-75 mg per week	600 mg/day

Procedures

There are few data to support the role of neuraxial corticosteroid injections, such as epidural steroids and nerve root blocks, in arachnoiditis treatment. Anecdotally, short-duration improvement may be observed, and any such procedures are usually performed as a "do and see" proposition.

The most promising intervention for the intractable pain associated with arachnoiditis is spinal cord stimulation. Spinal cord stimulation, also known as dorsal column stimulation, involves the placement of a stimulating electrode (either percutaneously or through a laminotomy)

FIGURE 95.3 Intraoperative placement of spinal cord stimulator leads.

over the dorsal aspect of the spinal cord (Figs. 95.3 and 95.4). Exact level and location of electrode placement depend on the location of the patient's pain. Typically, patients undergo a percutaneous trial to test the stimulator's efficacy before permanent implantation. The goal is to stimulate the spinal cord with low levels of electrical impulses that produce a nonpainful paresthesia that modulates (masks) the patient's pain.

The largest studies investigating spinal cord stimulation have included patients with varied diagnoses, the most

abundant of which is failed back surgery syndrome. It has been estimated that 11% of patients with failed back surgery syndrome have arachnoiditis. Approximately 50% to 60% of patients with failed back surgery syndrome treated with spinal cord stimulation receive more than 50% relief of their symptoms [9,10]. Studies investigating spinal cord stimulation efficacy in patients with a more specific diagnosis of epidural fibrosis or intradural fibrosis (arachnoiditis) have also found improvement in pain (60%), reduction of pain medication requirements (40%), and increased work capacity (25%) [11,12]. Spinal cord stimulation seems to be more effective for pain of neuropathic character than for pain of mechanical or musculoskeletal character. In addition, extremity pain is generally more easily treated compared with back pain–predominant symptoms [12].

Another option that could be considered is an intrathecal drug delivery system, which has been shown to be beneficial for those with chronic pain, whether it is neuropathic, nociceptive, or visceral in nature [13]. Medications such as opioids, local anesthetics, α -adrenergic receptor agonists, and NMDA receptor antagonists have all been successfully used. Recent use of intrathecal ziconotide has gained popularity for chronic neuropathic pain conditions. With all these interventions, one must consider the safety of the proposed treatment, taking special consideration of the risk of placing any intrathecal medication into an already pathologic spinal canal [13].

Surgery

There is very little role for surgical intervention in the treatment of arachnoiditis. There is no method of successfully surgically untangling the adherent nerve roots, although

FIGURE 95.4 Fluoroscopic lateral and anteroposterior images of a percutaneous spinal cord stimulator lead in the dorsal thoracic spine.

attempts have been made [14]. Indications for surgery include rapidly progressive neurologic deterioration, such as myelopathy due to progressive syringomyelia or cauda equina syndrome from arachnoiditis ossificans. In these instances, surgical intervention (shunt placement or removal of the calcific mass) could be contemplated. The emphasis on such interventions is to halt or to retard further neurologic deterioration. The prospect that such procedures will improve pain remains speculative at best. There has been some documentation of subarachnoid endoscopy (thecaloscopy) to perform adhesiolysis, but long-term benefit has not been established [15].

Potential Disease Complications

In severe cases of arachnoiditis, the fibrous bands that cause adherence of the nerve roots may become so prolific that progressive nerve root injury (radiculopathy, polyradiculopathy) or spinal cord injury (cauda equina syndrome, myelopathy) can ensue. Constriction of the spinal cord vasculature causes ischemia and focal areas of spinal cord demyelination. This vascular ischemia and associated alterations of normal cerebrospinal fluid flow have been observed to result in the formation of arachnoid cysts, syringomyelia, and even communicating hydrocephalus [16,17]. Calcification of the fibrotic milieu results in a condition termed arachnoiditis ossificans, which may result in progressive nerve root or spinal cord compression [18].

Potential Treatment Complications

Medication side effects are common. Anticonvulsant and antidepressant analgesics often produce sedation or alteration of mental status. Opiates, too, can produce sedation as well as severe constipation. Opiate dependence is generally anticipated as a ramification of use of this class of medication long term. Although true psychological addiction to opiates can occur, it is much less common than one might expect. The propensity for nonsteroidal anti-inflammatory drugs to cause gastrointestinal side effects is well known, as is their potential to adversely affect the kidneys and liver as well as to exacerbate hypertension and asthma.

Rehabilitation interventions are generally safe, although patients can suffer thermal injury from inappropriate application of superficial modalities. Transcutaneous electrical nerve stimulation and percutaneous electrical nerve stimulation are generally considered contraindicated in patients with pacemakers. Therapeutic exercise may potentially exacerbate pain symptoms.

Spinal cord stimulation poses some risk; however, complications are usually minor, and the incidence of new neurologic injury from something such as bleeding, infection, or neural trauma is quite small [10]. The most frequent complication usually entails electromechanical failure, such as percutaneous lead migration, when the stimulation no longer covers the symptomatic body region. The majority of electromechanical complications can be remedied with revision of the system.

G62.9 Polyneuropathy, unspecified
D49.9 and G63 Polyneuropathy, cancer related

Definition

Chemotherapy-induced peripheral neuropathy (CIPN) is damage and dysfunction of the peripheral nervous system secondary to chemotherapeutic agents, including platinum agents, taxanes, vinca alkaloids, thalidomide, bortezomib, and ixabepilone (Table 96.1). CIPN commonly occurs in 30% to 40% of patients, but its incidence can vary from 0% to 70% [1]. The degree of neuronal damage is dependent on many factors, such as the chemotherapeutic agent, the frequency and duration of therapy, the cumulative dose, the use of other neurotoxic agents, and the presence of preexisting neuropathies, most commonly from diabetes [1]. The severity of neuropathy generally increases until cessation of treatment. However, symptoms associated with platinum drugs may progress for weeks to months after treatment completion, a phenomenon called the “coasting” effect [2]. Many

scales have been proposed to assess CIPN but lack standardization and reproducibility. The most widely used tool is the National Cancer Institute Common Terminology Criteria for Adverse Events (v4.03) (Table 96.2) [3]. Another scale is called the Total Neuropathy Score, which appears to be more sensitive in detecting changes in CIPN [4].

Symptoms

The onset of symptoms can be sudden or slowly progress over time. Symptoms can vary by what types of nerve fibers are affected. Sensory nerves are more commonly affected first because they have small fibers, they have little capacity for regeneration, and their cell bodies are located in dorsal root ganglion, where they are outside the protective blood-brain barrier. The dorsal root ganglion has a high supply of capillaries that are highly permeable to toxic compounds in the blood [5]. Patients can present with symmetric, distal, length-dependent, “stocking-glove” distribution of painful paresthesia, dysesthesia, cold sensitivity, allodynia, tingling, and numbness. The patients also may report muscle cramps and pain described as burning, lancinating, shock-like, or electric. Motor nerve fiber cell bodies located in the spinal cord are less affected as they are protected within the blood-brain barrier and they also have the capacity for distal sprouting and regeneration. Patients usually present with muscle weakness, myalgias, and difficulty in walking. If autonomic nerves are affected, patients can present with orthostatic hypotension, constipation, urinary retention, irregular heart rate, and sexual dysfunction [6].

Physical Examination

Physical examination should assess for impairments with any sensory modalities, including light touch, pinprick, proprioception, and temperature. Deep tendon reflexes may be absent. Motor strength, gait, and balance deficits should also be evaluated in detail. Lhermitte sign, which is defined as eliciting an electric sensation running down the spine with neck flexion, may be present, especially after platinum compounds secondary to demyelination in the spinal cord [7].

Table 96.1 Most Common Chemotherapeutic Agents Known to Induce Neuropathy

Drug	Mechanism of Action
Platinum compounds (cisplatin, carboplatin, oxaliplatin)	Damages DNA in dorsal root ganglion, causing neuronopathy or ganglionopathy with sensory axonal neuropathy
Vinca alkaloids (vincristine, vinblastine, vinorelbine, vindesine)	Antimicrotubule agents that inhibit axonal transport, causing sensorimotor axonal neuropathy
Taxanes (paclitaxel, paclitaxel albumin-stabilized nanoparticle formulation [Abraxane], docetaxel)	

Table 96.2 National Cancer Institute Common Terminology Criteria for Adverse Events (v4.03), Motor and Sensory Combined

Grade	Description	Action
0	Normal	No intervention
1	Asymptomatic, clinical or diagnostic observations only, weakness on examination only, loss of deep tendon reflexes or paresthesia	No intervention
2	Moderate symptoms, limiting instrumental activities of daily living	Decrease dosage
3	Severe symptoms, limiting self-care activities of daily living, assistive devices indicated	Decrease dosage or discontinue treatment
4	Life-threatening consequences, disabling	Discontinue treatment, urgent intervention indicated
5	Death	

Functional Limitations

The severity of the symptoms can range from mild discomfort and pain to severe disability and paralysis, with reduced functional independence and reduced quality of life. Weakness and proprioceptive impairments in the lower extremities may cause difficulty with mobility, balance, and gait, resulting in an increased risk of falls and injury. Weakness and sensory impairments in the upper extremities may cause difficulties with fine motor activities such as buttoning, tying shoelaces, cutting food, opening medication containers, typing on a computer keyboard, or operating a cell phone.

Diagnostic Studies

There is no standardized or “gold standard” diagnostic study to evaluate CIPN. Objective assessment such as nerve conduction studies, electromyography, and quantitative sensory testing can assess function and type of nerve damage (axonal vs demyelinating). These findings correlate poorly with the patient’s report of symptoms, and changes in these tests can lag behind the onset of symptoms [7]. Other diagnostic

tests should be used to screen for other causes of neuropathy (complete blood count; erythrocyte sedimentation rate; C-reactive protein level; vitamin B₁₂, methylmalonic acid, homocysteine, and folate concentrations; comprehensive metabolic panel to evaluate fasting blood glucose concentration; renal function and liver function tests; thyroid function tests; serum protein immunofixation electrophoresis; urinalysis and urine protein electrophoresis with immunofixation; drugs and toxin screen; paraneoplastic panel) [8]. Magnetic resonance imaging can also be done to rule out compression neuropathies and radiculopathy.

Differential Diagnosis

Myelopathy
Radiculopathy or polyradiculopathy
Polyradiculoneuropathy
Plexopathy
Mononeuropathy (e.g., carpal tunnel syndrome)
Peripheral neuropathy due to nonchemotherapy causes

Treatment

Initial

The main treatment of CIPN is to discontinue the offending agent or to reduce the dosage or frequency of administration. However, altering the treatment regimen needs to be weighed against the overall efficacy in treating the underlying disease. Many agents have been studied for prevention of CIPN (such as vitamin E and glutamine) but need larger randomized placebo-controlled trials to be scientifically proven to be effective. Other agents, such as calcium and magnesium infusions, glutathione, and α -lipoic acid, are currently under clinical trial investigation. Aside from stopping or decreasing the dose of the chemotherapeutic agent, there are no agents specifically approved for treatment of CIPN. Many drugs are being used on the basis of their efficacy in reducing pain intensity for other types of neuropathic pain, such as diabetic neuropathy [9]. In particular, pregabalin [10] and duloxetine [11] have been shown in clinical trials to be efficacious in reducing the symptoms of CIPN. Other agents commonly used for neuropathy, which have not been scientifically proven to be efficacious for CIPN, include gabapentin, venlafaxine, tricyclic antidepressants (amitriptyline and nortriptyline), and opioids. Topical agents such as capsaicin and lidocaine patches have also been found to be effective in certain forms of peripheral neuropathy [12]. A more recent topical gel formula, BAK-PLO (baclofen, amitriptyline, and ketamine in pluronic lecithin organogel), has shown moderate improvement in CIPN pain symptoms [13]. Medications are usually helpful in relieving the positive symptoms of CIPN (pain, paresthesia, dysesthesia, allodynia) but not effective for the treatment of negative neuropathic symptoms (weakness, numbness, or proprioceptive loss). Although rare, autonomic symptoms such as hypotension can be treated with getting up slowly, maintaining adequate salt and water intake, and using abdominal binders and compression stockings to decrease venous pooling. Resistant cases can be treated with midodrine or fludrocortisone.

Rehabilitation

Rehabilitation is successful when it is focused on specific individual impairments and subsequent disability, which could include imbalance, weakness, gait abnormality, and loss of proprioception. There should be a detailed evaluation for need of assistive devices or orthotics to prevent falls and to improve ambulation. Environmental and home modifications (removing throw rugs, installing adequate lighting) should be implemented as well. Aside from improving hand dexterity, occupational therapists can help with adaptive equipment (enlarged handles on eating utensils, button-hooks) and increasing proprioceptive input, such as putting weights on the patient's arm.

Procedures

Neurostimulation with a transcutaneous nerve stimulation unit has been found to be helpful in some peripheral neuropathies but lacks sufficient evidence for treatment of CIPN. It can be used as an adjuvant therapy for patients with contraindications to pain medication or for whom it is ineffective, considering its ease of application and reversibility [6]. One small study suggested that acupuncture as a treatment of CIPN is effective in improving sensation, gait, and balance and that patients are able to reduce their use of pain medications [14]. There are no studies to date looking at the effectiveness of intrathecal medication delivery for the management of CIPN.

Surgery

Spinal cord stimulation has been reported to be successful in the treatment of many neuropathic pain syndromes [15] and should be reserved for patients with refractory pain. Spinal cord stimulation is a surgical procedure that involves placement of electrodes into the epidural space that send non-noxious electrical stimulation across the spine to displace painful sensations. This is used in refractory cases secondary to the risks and costs involved with the procedure.

Potential Disease Complications

Severe symptoms of CIPN can decrease a person's quality of life and impair activities of daily living. Also, CIPN can be a dose-limiting side effect that can interfere with the patient's ability to receive the full dose of cancer treatment or at a frequency required for optimal outcomes, which can eventually compromise survival.

Potential Treatment Complications

The main potential complication from the treatments or prevention of CIPN is the interference with the antineoplastic

efficacy of chemotherapy. Other treatment complications arise from the different medications and their respective side effects. Gabapentin may cause somnolence, dizziness, gastrointestinal symptoms, mild edema, and cognitive impairment. Pregabalin has side effects similar to those of gabapentin but milder. Its faster onset of action, better absorption, and less need for titration make it a more preferred drug of choice. Duloxetine can cause nausea, xerostomia, constipation, or diarrhea. Duloxetine should be avoided with other serotonin reuptake inhibitors to prevent serotonin syndrome and also should be avoided with tamoxifen as it can decrease tamoxifen's active metabolite. Tricyclic antidepressants are usually less tolerated secondary to side effects of dry mouth, drowsiness, weight gain, and orthostasis.

338.4 Chronic pain syndrome
338.29 Chronic pain

ICD-10 Codes

G89.4 Chronic pain syndrome
G89.29 Chronic pain

Definition

Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage [1]. Chronic pain is a pain status that persists beyond a reasonable expected healing period for the involved tissue. It is chronic if it persists for 6 months or more despite active treatment. It is called a syndrome because a constellation of symptoms develops in those patients facing chronic pain. The most common conditions leading to chronic pain syndrome (CPS) include headaches, repetitive stress injuries, back pain, whiplash injury, degenerative joint disorders, cancer, complex regional pain syndrome, shingles, fibromyalgia, neuropathy, central pain, and multiple surgeries [2]. In excess of 50 million Americans suffer from CPS and have a degree of impairment or disability from this condition [2]. Pain disorders cost \$100 billion annually in lost work days, medical expenses, and other benefit costs [2]. Chronic pain is often a hidden problem and may be an issue that individuals are reluctant to share with family or friends. This may have an impact on the awareness of CPS in the community at large.

Chronic pain is prevalent in both adults and the pediatric population. Children suffering from chronic pain frequently continue to suffer from chronic pain as adolescents and young

adults [3]. Some authors have reported a higher prevalence of CPS in individuals with a history of childhood abuse and personality disorder (borderline, narcissistic) [4]. CPS is more prevalent in women and by up to twofold in some diagnoses (e.g., fibromyalgia) [5,6]. Studies suggest a relationship between chronic pain and race as well as socioeconomic status. In a study of 3730 adults between ages 18 and 49, African Americans appear to have significantly more pain and disability and live in lower socioeconomic neighborhoods [7]. Living in a lower socioeconomic status neighborhood was associated with increased sensory, affective, pain-related disability and mood disorders [7].

Given its unclear pathophysiology and the lack of a definitive diagnostic test or successful treatment, CPS imposes a challenge to health care providers. Most patients are often unsatisfied with the treatment outcomes, leading to psychosocial stress, chronic pain behaviors, medication seeking, impairment, activity restriction, limited participation, and disability.

Symptoms

The primary symptom is a protracted pain that is out of proportion to the objective pathophysiologic process. Table 97.1 shows a list of common associated symptoms. Pain may be localized to a body segment, or it could be widespread. The measurement of pain severity is subjective and typically relies on the patient's report as well as on functional ability (work, activities of daily living, hobbies). The numeric (0-10) or the visual analogue scale that is used to assess pain often does not properly reflect the pain intensity, and despite adjustments to medical management, the reported pain level is unchanged. Because of this, clinicians may focus on functional gains as a measure of treatment success rather than on the patient's report of a decreased numeric or visual analogue scale score.

In CPS, there are often associated *pain behaviors* that help establish the diagnosis. Pain behaviors include assuming poor posture, abnormal gait (limping), facial grimacing, stiff movements, and use of assistive devices that have not been medically prescribed (canes, wheelchairs, and electric scooters). Decreasing pain behavior decreases the experience of pain. Behavioral treatments are a key component of multidisciplinary pain programs and can be effective for the relief of pain.

Mood and affect disorders including depression, anxiety, emotional instability, and anger are commonly associated

Table 97.1 Common Associated Symptoms and Signs in Chronic Pain Syndrome

Depression	Sleep disorders
Anxiety	Irritable bowel
Emotional lability	Cognitive difficulty (memory, concentration)
Chronic fatigue	Pain behaviors
Medication seeking	Dramatization of symptoms
Doctor shopping	Legal action—secondary gain

symptoms in patients with CPS [8]. Some studies have reported up to fourfold increased depression in patients with chronic back pain [9]. Chronicity of the pain, lack of clear etiology, and poor treatment outcomes contribute to the emotional aspect of this disorder. Just treating pain with medications without addressing the psychosocial component will lead to poor outcomes and further suffering. Part of the reasonable success associated with the multidisciplinary pain programs is related to management of the psychosocial component of the chronic pain.

Sleep disorders are prevalent in patients with CPS. Studies have shown that severity of insomnia contributes to the prediction of pain severity [10]. The insomnia associated with chronic pain needs to be anticipated and treated. Sleep-inducing medications often combined with cognitive-behavioral therapy can help improve insomnia. Sleep education, cognitive control and psychotherapy, sleep restriction, remaining passively awake, stimulus control therapy, sleep hygiene, relaxation training, and biofeedback are part of the cognitive-behavioral approach to treatment of insomnia [11]. Clinicians should be aware of increased cognitive impairment in elderly patients treated with medications for insomnia. This may lead to falls, injury, and increased pain [12].

Physical Examination

Physical examination is directed toward finding treatable causes of CPS. One of the most important parts of the physical examination is to observe the patient's gait, body motion, posture, and facial expression as well as abnormal pain behaviors. A systematic and detailed musculoskeletal and neurologic examination needs to be conducted. If the CPS follows an injury, focused examination of the injured body part is needed. Give-away weakness, nonmyotomal weakness, and nondermatomal numbness are often encountered on physical examination. If it is done repeatedly, there are likely to be inconsistencies in physical examination findings of a patient with CPS. Redirecting the patient's attention while repeating the examination may alter the findings and can point to pain behaviors. For example, diffuse tender points may not be tender if the patient's focus is diverted. Another example is a negative result of the seated straight-leg test (patients are less knowledgeable about it) versus a positive result of the supine straight-leg test in the same patient.

There are diagnosis-specific examination findings that may be noted, such as allodynia and trophic changes. These may be found in the area of the initial injury or in a different body part. Depending on the complaint, examination of other systems, including gastrointestinal, urologic, and pelvic girdle, may be indicated.

Functional Limitations

Typically, there is a disproportionate loss of function in patients with CPS when it is matched to the injury and the stated age. Fear-avoidance behavior will result in deconditioning and decline in function with activities of daily living [13]. Deconditioning leads to increased perception of pain, reduced quality of life, and further psychosocial stress and disability. If such abnormal pain behavior is reinforced by health care providers or the patient's family, it will result in chronicity of the pain and further decline in function.

Diagnostic Studies

In CPS, diagnostic studies are performed to find treatable causes that can lead to lingering pain. The results of such studies are often inconclusive or normal. Diagnostic testing may include laboratory work, electrodiagnostics, and imaging. Unless the presenting symptoms have changed, repeating costly diagnostic tests is of no value. Equally important is psychological testing. The Minnesota Multiphasic Personality Inventory is the most common psychological test used in patients with chronic pain and has been shown to help understand pain behaviors and the psychological impact on individuals with chronic pain [14] (Table 97.2).

Table 97.2 Differential Diagnosis of Chronic Pain Syndrome

Disorder	Description
Somatoform disorder	Group of psychiatric disorders, including somatization disorder, conversion disorder, hypochondriasis, and factitious disorder, that cause unexplained physical symptoms
Somatization disorder	Chronic physical symptoms that involve more than one part of the body, but no physical cause can be found Pain complaint is often associated with gastrointestinal, pseudoneurologic, and sexual complaints Symptoms are not intentionally fabricated
Conversion disorder	Dramatic loss of voluntary motor or sensory function (e.g., inability to walk, sudden blindness, paralysis) No evidence that the symptom is feigned or intentionally produced; loss of function is not due to medical illness
Hypochondriasis	Excessive preoccupation or worry about having a serious illness in absence of an actual medical condition
Factitious disorder	Deliberately produces or falsifies symptoms of illness for the sole purpose of assuming the sick role
Malingering	Fabricating or exaggerating the symptoms of mental or physical disorders for a variety of secondary gain motives

Differential Diagnosis

Somatoform disorder
Somatization disorder
Conversion disorder
Hypochondriasis
Factitious disorder
Malingering

Treatment

Initial

The initial treatment focuses on management of the pain and improvement in function. Numerous studies suggest a multidisciplinary approach for management of CPS [15]. These studies show that multidisciplinary treatments of chronic pain are superior to single-discipline treatments, such as medications or physical therapy. A team approach focuses on supporting patients in reaching individual goals. Goals should be improving pain and a better quality of life by means of enhancing physical and psychosocial function. The beneficial effect of multidisciplinary treatment is not limited to improvements in pain but also extend to variables such as return to work and use of the health care resources. An anesthesiologist, John J. Bonica, was the first to appreciate the need for a multidisciplinary approach to chronic pain [16]. Members of a multidisciplinary pain management team include a pain medicine specialist, mental health specialists, a physical therapist, an occupational therapist, the primary care provider, and the patient. Ideally, the rehabilitation component is 2 to 3 hours per day, 3 days per week, for several weeks [17]. In addition, patients will see mental health counselors weekly and are monitored by the pain specialist who is overseeing the entire care.

Education of the Patient

It is crucial for the patients dealing with CPS to be educated in the complexity of the disorder and possible factors affecting its management. Patients should be knowledgeable about their participation in the treatment plan. Both patient and family should have a good understanding of the multifactorial nature of chronic pain and the benefits of multidisciplinary management. Education of the patient should be done by all members of the treatment team.

Mental Health Treatment

Psychological interventions help patients find ways to accept the condition and to adjust to it. The focus of mental health counseling is to work on pain behaviors and to educate patients about the adverse consequences of this atypical behavior. Patients need to understand that negative thoughts stemming from pain will influence mood, behavior, sleep, and chronicity of the pain. Individual or group treatment may include biofeedback, relaxation training, coping mechanisms, clinical hypnosis, and cognitive therapy techniques [18]. These options may result in improved ability to manage pain. Advanced psychological or psychiatric treatments may include pharmacologic interventions to address emotional problems, affect disorders, anxiety disorders, sleep disturbances, and panic attacks. Common medications to

Table 97.3 Common Medications Used to Address Psychological Issues in Chronic Pain Syndrome

Class	Examples
Antidepressants	Amitriptyline, nortriptyline, clonazepam, venlafaxine, citalopram, fluoxetine, bupropion, escitalopram, sertraline
Anxiolytics	Lorazepam, clonazepam, oxazepam, diazepam, alprazolam, buspirone
Mood stabilizers	Divalproex, lithium, gabapentin

treat psychological disorders in CPS are listed in [Table 97.3](#). If opioid medications are being considered for treatment of CPS, a consultation with a pain psychologist is indicated to determine risk of future abuse.

Medications

In CPS, pain medications and adjunct medication are often not able to eliminate pain, but the analgesic effect may lead to increased function, improved rehabilitation outcomes, restored sleep, and enhanced mood. Commonly used pain medications and adjunct pharmaceutical substances in CPS are listed in [Table 97.4](#). Pain medicine specialists should evaluate the patient, prescribe appropriate medications, monitor use and effect, and make adjustments when necessary. Short-term use of medications for pain is rarely worrisome, but prolonged use may increase the possibility of adverse reactions, including gastrointestinal side effects, cognitive and memory deficits, and gait instability. Use of opioid analgesics for chronic pain, although controversial, is fairly common. Opioid analgesics must be used with utmost caution and with understanding of the challenges related to chronic opioid management as well as the social stigma attached to them. The author recommends an opioid contract

Table 97.4 Analgesics and Adjunct Medications Prescribed for Chronic Pain

Class	Medication
Nonsteroidal analgesics	Salicylates: aspirin Arylalkanoic acids: diclofenac, etodolac, indomethacin, nabumetone Arylpropionic acids: ketoprofen, ibuprofen, naproxen Oxicams: piroxicam, meloxicam Coxibs: celecoxib
Opioid analgesics	Codeine, meperidine, hydrocodone, hydromorphone, morphine (short and long acting), oxycodone (short and long acting), methadone, fentanyl, tramadol, tapentadol
Partial μ opioid agonist and κ opioid receptor antagonist	Buprenorphine
Adjunct medications	Antiseizure medications: pregabalin, gabapentin, lamotrigine, topiramate, clonazepam Antidepressants (see Table 97.3)
Sedatives	Benzodiazepines: temazepam, diazepam, lorazepam Nonbenzodiazepines: eszopiclone, zaleplon, zolpidem

and involvement of the primary care physician in decision-making. Frequent and random blood or urine drug testing (for narcotic and illicit drugs), pill counts, opioid rotation, and routine reevaluation are needed to ensure safe use and effective treatment. Currently available evidence suggests that cannabis treatment is moderately efficacious for certain types of chronic pain (e.g., neuropathic, multiple sclerosis), but beneficial effects may be offset by potentially serious harms [19,20]. Smoked cannabis reduces pain, improves mood, and helps sleep in such patients [20]. More evidence from larger, well-designed trials is needed to clarify the true balance of benefits and harms.

Rehabilitation

Both outpatient and inpatient models of care are available to manage chronic pain, although it is difficult to obtain insurance coverage for inpatient care. This population of patients starts from a lower functional level, so the duration of treatment could be longer than the average for musculoskeletal pain issues. The rehabilitation team (physical therapist, occupational therapist, recreation therapist) will work with the patient to establish a structured day including supervised exercises. The basic exercise structure will include conditioning, stretching activities, progressive core and generalized strengthening, and aerobic exercise training. Aerobic exercise can be performed in an aquatic environment. The focus will also be on correction of body mechanics, proper posture, restoration of function, modification of maladaptive behaviors, and provision of pain relief by incorporation of modalities (heat, ice, and ultrasound) and relaxation techniques [21]. Deep tissue massage, myofascial release, transcutaneous electrical nerve stimulation, Pilates, Tai Chi, and yoga are additional treatments offered to patients with chronic pain. The accumulating evidence from recent reviews suggests that acupuncture is more than a placebo for commonly occurring chronic pain conditions [22]. Manipulative therapy, within the context of interdisciplinary treatment, has been shown to be an efficient and effective treatment to improve pain and function in patients with mechanical or compressive pain [23]. Transcutaneous electrical nerve stimulation units help relieve pain and foster independence in patients with chronic pain [21].

A recreational therapist examines previous interests of the patient and barriers to return to leisure activities. Within a formal program, recreational therapists evaluate and plan leisure activities that serve to promote mental and physical health. The challenge for the rehabilitation team remains the fear-avoidance behavior.

Procedures

Depending on the pain generator, specific procedures may help patients with CPS. This is especially true if previous medical care has insufficiently addressed the symptoms. Procedures that may be effective include neuraxial blocks, facet injections, radiofrequency neurotomy, sacroiliac injection, peripheral joint injections, peripheral nerve blocks, acupuncture, trigger point injections, and infiltration of inflamed bursa or tendons. Image guidance will enhance the accuracy of spine injections and will lead to improved outcome [24,25]. Chronic pain of complex regional pain

syndrome (see Chapter 99) may be addressed with neuromodulation by spinal or peripheral nerve stimulator implantation. Implantable pain pumps are indicated in pain associated with terminal cancer but may also have limited indication in difficult to control pain of noncancer origin. When relative pain relief is achieved with procedures, tapering pain medications as well as increasing intensity of the rehabilitation program is encouraged.

Surgery

There is a limited indication for surgery in chronic pain. If the pain generator is identifiable and modern surgical methods are available to treat it, surgery may be considered. Patients suffering from chronic discogenic low back pain may benefit from interbody fusion or disc arthroplasty. Patients with end-stage degenerative joint disease suffering from chronic pain would likely benefit from arthroplasty. When it is clinically indicated and other noninvasive treatments have failed to help, an intrathecal drug delivery system and spinal or peripheral nerve stimulators could be considered, both of which require surgical implantation. It is possible that despite a surgical solution, the patient will continue to suffer from chronic pain.

Potential Disease Complications

Significant disability secondary to pain as well as suicidal ideation or attempt (secondary to psychosocial comorbidities) may complicate the clinical picture.

Potential Treatment Complications

Medications used to treat chronic pain can result in class-specific side effects. Nonsteroidal anti-inflammatory drugs commonly have gastrointestinal and renal side effects. Muscle relaxants, serotonin-norepinephrine reuptake inhibitors, anxiolytics, and tricyclics can cause central nervous system suppression. Narcotics can result in nausea, constipation, respiratory suppression, mental status changes, and suppressed endogenous opioids; dependency, tolerance, and abuse may also develop. Rehabilitation program intensity that is disproportionate to the functional status of the patient may lead to dissatisfaction and poor compliance and can worsen fear-avoidance behavior. Interventions and surgical care have their specific potential complications.

Acknowledgment

The author would like to thank resident physician Tony George for his valuable time and assistance in gathering updated literature on chronic pain syndrome.

724.79 Coccydynia, coccygodynia

ICD-10 Codes

K59.4 Proctalgia fugax
M53.3 Coccydynia

Definition

Coccydynia is pain in the vicinity of the coccygeal bone at the base of the spine. It may be localized to the lower sacrum, the coccyx, or the adjacent muscles or soft tissues. Pain can be insidious or sudden in onset. Symptoms are usually triggered by sitting or rising from a sitting position.

The mean age at onset of coccydynia is 40 years, but it can occur over a wide range of ages [1]. The most common inciting factor is trauma to the coccyx or surrounding soft tissue from a vertical axial blow or cumulative trauma from a difficult vaginal delivery. Pathologic features may range from dislocated sacrococcygeal fracture to ligamentous damage of the caudal coccygeal segments. In most cases, the tip of the coccyx is subluxated or hypermobile [1] (Figs. 98.1 and 98.2).

The coccyx consists of three to five rudimentary vertebrae. The first coccygeal segment has transverse processes that articulate and occasionally fuse with the sacrum. This vertebra is usually separate from the remaining coccygeal

vertebrae, which may partially or completely fuse, leading to anatomic variation of one to four total bony coccygeal segments [2].

The fibrous sacrococcygeal symphysis connects the sacrum to these segments of the coccyx. This joint is reinforced by sacrococcygeal ligaments, which enclose the final intervertebral foramen through which the S5 roots exit. The S4, S5, and coccygeal roots contribute to the coccygeal plexus, which provides rich somatic and autonomic innervation to the anus, perineum, and genitals [3]. The levator ani (innervated by S3-S5 nerve root branches through perineal and inferior rectal nerve branches of the pudendal nerve [4]) and coccygeal muscles (innervated by S3-S5 nerve root branches [5]) attach to and support the coccyx during defecation and childbirth. The gluteus maximus also attaches to the lateral coccyx and can contribute to a sensation of pressure while sitting.

Morphology of the coccyx may have a role in coccydynia. The coccyx that is markedly curved or angled forward, is anteriorly subluxed [2], or contains a bone spicule [6] is more prone to pain. Degeneration of disc structures [7] and referred pain from lumbar disc disease [2] have been implicated. There are also reported cases of rare coccydynia pathologic processes, including tuberculosis, tumors, and calcification of the joints or tendons. Prevalence of coccydynia is four to five times higher in women than in men [8,9]. In addition to obstetric trauma [10], the increased susceptibility to injury in women is attributed to anatomy as the female coccyx is more posterior in location and larger than the male coccyx [11]. Coccydynia is three times more frequent in obese women than in nonobese women [6], and this may be related to decreased pelvic rotation while sitting.

Symptoms

Coccygeal pain is located at the tip or sides of the coccyx. The quality of pain is usually dull and achy at baseline and intermittently sharp during activities that aggravate the symptoms. A sensation of pressure or an urge to defecate is also commonly described. Coccydynia has been associated with dyspareunia, dyschezia, dysmenorrhea, and piriformis syndrome. Symptoms are usually exacerbated by sitting on hard surfaces, prolonged sitting, and moving from the sitting to the standing position. Symptoms are generally relieved by taking weight off the coccyx.

Levator ani syndrome and proctalgia fugax are variants of coccydynia.

FIGURE 98.1 Lateral radiographs of coccygeal subluxation. (From Doursounian L, Maigne JY, Faure F, et al. Coccygectomy for instability of the coccyx. *Int Orthop* 2004;28:176-179.)

Levator ani syndrome is a dull ache or pressure sensation in the rectum, with pain episodes lasting more than 20 minutes at a time. Symptoms tend to be more severe during the day than at night. Symptoms may result from a hypertonic levator ani or puborectalis muscle or from inflammation of the arcus tendon of the levator ani [12,13]. This syndrome is associated with posterior traction of the puborectalis muscle and levator ani muscle tenderness on rectal examination.

Proctalgia fugax is the sudden onset of excruciating anal pain lasting a few seconds or minutes, then disappearing completely. Proctalgia fugax is characterized by spastic muscle contractions of the pelvic floor [14]. Episodes usually occur fewer than five times a year [15]. Symptoms are not typically related to defecation but are associated with sexual intercourse. Symptoms are usually nocturnal and awaken the patient from sleep. Unlike coccydynia, which is more common in women, proctalgia fugax occurs equally in men and women.

Physical Examination

- Inspect the sacrococcygeal region including the anus, surrounding skin, and soft tissue for cysts, fistulas, external hemorrhoids, and fissures.
- Palpate the pelvic area for evidence of lymphadenopathy or pelvic masses to rule out neoplastic or infectious disease (see the section on differential diagnosis).

FIGURE 98.2 Sagittal magnetic resonance image of misaligned coccygeal fracture. (From Pennicamp PH, Kraft CN, Stuetz A, et al. Coccygectomy for coccygodynia: does pathogenesis matter? *J Trauma* 2005;59:1414-1419.)

- Assess for point tenderness or palpable abnormalities along the pelvic girdle, including the tip of the coccyx where a spicule would be located. It is also important to palpate surrounding joints. Classic findings in coccydynia are exquisite tenderness to direct palpation of the coccyx, sacrococcygeal ligaments, and pubococcygeal ligaments.
- Evaluate leg lengths, pelvic obliquity, sacroiliac motion, and sacroiliac joint tenderness because correction of these problems may be part of the treatment.

Lower extremity strength, reflexes, and sensation should be assessed for focal neurologic deficits and should be normal in coccydynia.

Digital rectal examination should include testing for occult blood, palpation for internal masses, and palpation of the levator ani muscles for tenderness. Manipulation of the coccygeal tip, the pubococcygeal ligament, and the sacrococcygeal joint should be performed to assess for tenderness and hypermobility [16].

Functional Limitations

Because coccydynia is often worsened by sitting, driving can become very painful. Sedentary work involving prolonged sitting may exacerbate symptoms; frequent breaks may be required. It is common to avoid social situations because of pain when sitting. Because of pressure to the coccyx and muscle contractions in the perineum during orgasm, sexual intimacy can worsen symptoms and is often avoided. Equestrian activities, cycling, and contact sports can also be particularly painful.

Diagnostic Studies

Coccydynia is often associated with subluxation or hypermobility of the tip of the coccyx (Fig. 98.3), which is usually seen on dynamic radiographs [1,17]. Single-position radiographs are seldom helpful in differentiating morphologic differences. Dynamic lateral radiographs are obtained in lateral and oblique views while the patient is sitting and standing. These demonstrate pelvis rotation and coccygeal mobility and may show fusion of the sacrococcygeal joint and superior intercoccygeal joints [1,17].

Bone scans and magnetic resonance imaging may show inflammation, fracture, or bone fragments. Because they are static tests, they are no more useful than dynamic radiographs in the diagnosis of hypermobility or subluxation [1]. However, advanced imaging modalities such as magnetic resonance imaging may be useful as second-line imaging to detect pericoccygeal inflammatory reactions, bone signal changes and edema, disc changes, or coccygeal tumors [18]. This may be clinically informative and guide treatment when dynamic radiographs are unremarkable.

Anal manometry testing has been described in the literature, with conflicting reports on its utility. The basis for manometry testing is the theory that prolonged sphincter contraction or dystonia may contribute to coccygeal pain. Abnormal anal manometric pressures support a diagnosis of proctalgia fugax, but the test is unlikely to diagnose proctalgia fugax because episodes are so infrequent. Anal manometry is not routinely recommended in the evaluation of coccydynia.

Differential Diagnosis

Coccygeal fracture, ligamentous strain, or dislocation
Bursitis at the coccygeal tip
Post-traumatic sacrococcygeal osteoarthritis
Coccygeal or lumbar disc degeneration
Internal pudendal nerve entrapment (Alcock canal syndrome)
Lower sacral nerve arachnoiditis
Rectal fissure
Pelvic or perirectal abscess
Pilonidal cyst or sinus
Thrombosed external hemorrhoid
Prostatitis
Pelvic organ prolapse
Tumors of the colorectum, sacrum, prostate, or ovaries
Postsurgical adhesion

Treatment

Initial

Conservative treatment is the “gold standard” for coccydynia as the natural history does not usually lead to deterioration. Medication management includes topical perianal

FIGURE 98.3 Schematic drawing of flexion mobility of the coccyx. **A**, Normal standing appearance of the coccyx. **B**, Increased flexion mobility of the coccyx when the patient is seated. **C**, Posterior subluxation of the coccyx when the patient is seated. **D**, Coccygeal spicule (arrow) arising from the dorsal surface of coccygeal segment. (From Fogel GR, Cunningham PY, Esses DI. Coccygodynia: evaluation and management. *J Am Acad Orthop Surg* 2004;12:49-54.)

lidocaine cream or gel, a bowel regimen or laxatives, acetaminophen, and nonsteroidal anti-inflammatory drugs.

Although they are relatively safe interventions, the efficacy of sitz baths, muscle relaxants, anticonvulsants, tricyclic antidepressants, acupuncture, iontophoresis, biofeedback, and electrogalvanic stimulation has not been established in the literature.

Rehabilitation

Ergonomic adaptation is commonly recommended. A trial of a doughnut-shaped pillow is always worthwhile to offload weight on the coccyx while sitting. Lifestyle recommendations, such as refraining from cycling, equestrian sports, or contact sports, may be beneficial.

Physical therapy should include pelvic massage and manipulation, pelvic relaxation techniques, pelvic floor strengthening exercises, pelvic joint mobilization, and postural correction. In patients with proctalgia fugax and levator ani symptoms, emphasis is placed on pelvic floor relaxation techniques. Correction of leg length discrepancy can help with referred sacroiliac pain. Psychological support is also crucial.

Procedures

Injection of the sacrococcygeal ligament and coccyx tip with 1% lidocaine can be diagnostic. A mixture of steroid (40 mg methylprednisone) and a long-acting anesthetic (0.25% bupivacaine) may be used for therapeutic purposes [19]. This procedure can be done with use of physical landmarks. Ultrasound-guided injection can be considered but has not been well documented. Fluoroscopic guidance has been used, but utility may be limited as visualization of ligaments is not possible.

If there is dislocation of the coccyx, manipulation under anesthesia may be helpful, but there are no conclusive data on the efficacy of this approach.

Botulinum toxin injection of the puborectalis and pubococcygeus muscles may relieve pain associated with muscle hypertonicity [20,21].

Prolotherapy is an injection of proliferant solution that may relieve the pain of enthesopathy and facilitate regeneration of torn or painful sacrococcygeal and pubococcygeal ligaments. Its safety is well established. Although there are no randomized studies, a prospective observational study using dextrose prolotherapy for recalcitrant coccydynia indicated relief in 30 of 37 patients [22].

More recently, there has been some reported success with interventional procedures, such as ganglion impar nerve block or radiofrequency ablation. The ganglion impar (also known as ganglion of Walther) is a solitary structure in the precoccygeal space at the caudal end of the sympathetic chain implicated in nociceptive and sympathetic supply to the perineum. Various techniques including transcoccygeal and extracoccygeal approaches under fluoroscopy, ultrasonography, or computed tomography guidance have demonstrated pain relief in small prospective studies of patients with chronic perineal pain or coccydynia [23,24].

Pulsed radiofrequency has also been investigated for coccydynia. A prospective trial of 21 patients with coccydynia refractory to conservative management showed excellent to good results in 81% of patients [25].

These procedures may be considered possible alternatives to surgery.

Surgery

Most people recover with conservative treatment alone within weeks to months. A number of uncontrolled studies of patients with refractory coccydynia report pain relief with partial and total coccygectomy [1,26–30]. Successful treatment is usually associated with abnormal coccygeal motion.

Potential Disease Complications

Coccydynia is a symptom and not a disease. The primary complication is functional decline secondary to local pain, generally limiting sitting tolerance, sexual intercourse, and exercise tolerance.

Potential Treatment Complications

Gastrointestinal, hepatic, and renal complications may arise from prolonged use of acetaminophen or nonsteroidal anti-inflammatory drugs. Steroid injections may also be complicated by skin depigmentation and transient elevation in blood glucose level. Repeated steroid injections may result in ligamentous breakdown and altered mobility in the sacrococcygeal ligament. All procedures, including injections, nerve blocks, pulsed radiofrequency, and surgery, may result in infections. Coccygectomy complications also include bleeding or hematoma, delayed wound healing, and wound dehiscence [9].

Definition

Complex regional pain syndrome (CRPS) is a perplexing medical condition. CRPS begins when a patient has an injury—to a nerve, bone, soft tissue, or connective tissue. The injury heals as assessed by both clinical examination and imaging, yet the patient still has pain significantly out of proportion not only to the healed injury but at times even to the injury itself. In addition to pain, the patient can have hyperesthesia or allodynia at the site of the injury. Curiously, the temperature of the affected limb can be different from that of the other side, and there can be hair, nail, and skin changes. In some cases, these changes can spread beyond the injury site to the entire limb, and in the worst case, in addition to excruciating pain and hyperesthesia, the skin becomes pachydermic.

Before 1994, this bizarre disease and constellation of symptoms was known, among other names, as reflex sympathetic dystrophy. Despite this moniker, it was never proved that the sympathetic nervous system mediates all the components of the disease, nor was a peripheral reflex or feedback loop causing the disease found. In 1994, a conference was held to clarify the classification of the disease [1]. It was renamed CRPS with two classifications, CRPS II for apparent major nerve injury and CRPS I for no major nerve injury. The disease is complex, and

it can often be regional rather than confined to a dermatome, myotome, or territory of a single peripheral nerve. Pain is the hallmark of the disease and, for a patient with history of an injury, the *sine qua non* of diagnosis. It is multifaceted.

The new name, interestingly, is less specific than the former name, expressing the current lack of a full understanding of the disease. More than a decade ago, one of us (V.S.R.) suggested that central remapping of sensory neurons in the cerebral cortex in response to a peripheral injury to the corresponding body area might be a root cause of pain and ultimately other problems in this condition [2]. This hypothesis has not only collected evidence since but led to new and potentially most useful treatments [3].

CRPS is relatively rare. Even with fracture, the most common inciting event, only 1% of patients develop CRPS [4]. The incidence has been estimated to be up to 26 per 100,000 person-years [5]. The incidence of CRPS type I is generally higher than that of CRPS type II. The lower extremity is more often affected than the upper extremity. Female sex, adult age, postmenopausal status, and smoking are all risk factors for its development [6]. In the pediatric population, the incidence of CRPS increases just before puberty [7].

The pathophysiologic mechanism of the disease is, again, poorly understood. There is emerging evidence that CRPS does not only affect the peripheral nervous system. Functional and structural reorganization [8] of the central nervous system has been demonstrated with functional magnetic resonance imaging [9], single-photon emission computed tomography, electroencephalography, and transcranial magnetic stimulation mapping. Neuroplasticity of both the cortical somatosensory [10] and motor [11] systems is implicated. Distorted sensory and motor mapping is hypothesized to promote spontaneous pain and neglect symptoms in CRPS.

Symptoms

CRPS is a clinical diagnosis. The diagnosis can be suggested by the history of present illness alone. An individual experiences an injury. The injury can come in a variety of forms, whether traumatic (e.g., crush injury, gunshot wound, burn, or protracted labor [12]) or non-traumatic (e.g., leprosy [13]). The “injury” can also be an otherwise uncomplicated surgery. While healing takes place, the individual develops pain variably progressive in intensity, area involvement, and duration. Patients with both CRPS type I and type II may report neuropathic pain that is often intense, constant, burning, and present even without stimulation or movement. Symptoms are not confined to a particular nerve or anatomic territory; CRPS can spread [14] to the contralateral limb and even progress to all four limbs. In addition to pain, motor complaints are common and include weakness, cramps, and stiffness. There may also be signs of neglect [15], or more subtly, some patients may refer to the affected limb in the third person (e.g., “it is not moving”). It is important to ask about abnormal sweating patterns, localized edema, and skin flushing as clues of autonomic dysfunction in the history.

Symptoms and signs of CRPS are historically grouped into three stages. Stage 1 consists of severe pain and inflammatory signs (e.g., pitting edema, rubor, increased hair and nail growth). Stage 2 is marked by more intense pain, brawny edema, pallor, ridged nails, and osteoporosis. Unyielding pain and irreversible skin and bone changes (e.g., dystrophy, contracture, and extensive osteoporosis) are the primary features of stage 3. Although CRPS does not always follow a stepwise progression, these stages are useful descriptively. Classifying the syndrome solely on the basis of the severity of pain (i.e., mild, moderate, and severe) may be appropriate to follow its clinical course over time. We also classify CRPS as irreversible (i.e., presence of pachydermic skin changes) or potentially fully reversible (i.e., absence of pachydermic skin changes).

Mood disturbance is common in the chronic stages of the illness. Patients often report anxiety as the disease progresses beyond the second month; and by the sixth month, all patients will exhibit varying degrees of depression, sleep disturbance, and anxiety [16].

Physical Examination

Begin the examination by inspecting for signs of injury at or near the affected site. The injury may have been long ago and only a scar remains. If possible, compare all findings with the contralateral side to identify subtle asymmetry. Look for evidence of autonomic disturbances that are manifested as localized edema, skin color changes, and abnormal sweating pattern; note that skin color is best observed under natural light. Late-stage CRPS is characterized by trophic changes, such as abnormal hair and nail growth, thin and shiny skin, and fibrosis. At rest, disuse atrophy is the most apparent motor disturbance, but spontaneous muscle fasciculation, tremor, and cramp in the supporting muscles of the limb may also be observed.

Proceed to gentle palpation of the affected area. Make note of marked temperature asymmetry. Studies have shown that a clinician can adequately identify temperature and limb circumference asymmetry without special instruments [17]. Nonetheless, an infrared thermometer or a surface-probe thermometer can give more precise measurements. A temperature difference of more than 1.1°C between the affected area and a nonaffected, homologous body part is significant [1], but clinicians should have a low index of suspicion for CRPS such that even a small temperature change may be clinically relevant. Next, estimate the extent of involvement by sensory disturbances, such as increased sensitivity (hyperesthesia), exaggerated pain response to a painful stimulus (hyperalgesia), pain to an innocuous stimulus (allodynia), and paradoxically in some patients, hypoesthesia [18]. Ascertain abnormal findings with repeated testing. The sensory examination includes tests for light touch, pinprick, temperature, vibration, and proprioception. Consider testing the forehead because sensory disturbances on the ipsilateral side have been described [19].

Have the patient actively range the affected joints. Make note of difficulty with initiation of motion and range of motion deficits, which in turn require passive range to assess

for contracture. The clinician can then perform a thorough musculoskeletal and neurologic examination including strength, stability, and reflexes to assess for deficits, be they related or unrelated to the CRPS.

Functional Limitations

The most immediate effects are dysfunction in activities of daily living from disuse of the affected limb. Lower limb involvement results in gait impairment. Even properly treated patients may continue to experience disability and decreased quality of life in the long term [20]. Permanent disability may ensue if contracture develops over time. Chronic pain also leads to the well-known syndrome of deconditioning, sleep disturbance, anxiety, and depression. With inadequate treatment, quality of life can be severely affected, often with devastating social, recreational, financial, and vocational consequences.

Diagnostic Studies

Several sets of diagnostic criteria (e.g., Bruehl and Veldman) exist, and none has been shown to be superior [21]. The International Association for the Study of Pain (IASP) criteria are most widely referenced in the literature and made up of the following four components: (1) presence of an identifiable noxious event or cause of immobilization; (2) persistent pain, allodynia, or hyperalgesia, disproportionate to any inciting event; (3) edema, changes in skin blood flow, or abnormal sudomotor activity; and (4) exclusion of other diagnoses as the cause of these symptoms [1]. IASP criteria are notably limited by poor inter-rater reliability and a specificity of only 36% [22]. They were subsequently revised in 2003 and published in 2007 as the Budapest criteria, which boast an increased specificity [23]. The Budapest criteria replace the second and third components of IASP criteria with at least one symptom and one sign in three of the following four categories: sensory, vasomotor, sudomotor or edema, and motor or trophic changes.

There is no “gold standard” for diagnosis of CRPS. It is a diagnosis of exclusion. Electromyography and nerve conduction studies can help identify nerve injury, if there is clinical suspicion. Doppler flowmeter, vascular scintigraphy, and vital capillaroscopy evaluate for vasomotor changes. Quantitative sudomotor axon reflex testing measures sweat output after mild electrical stimulation.

Plain films are often normal early in the course. Demineralization may become evident by the second month. Magnetic resonance imaging demonstrates nonspecific marrow edema, soft tissue swelling, and joint effusion. Even bone scintigraphy, in which the most suggestive finding is increased periarticular activity in the affected limb, has variable sensitivity and specificity [24]. A recent meta-analysis supports the use of triple-phase bone scan for assessment owing to its high sensitivity and negative predictive value [25].

Workup should focus on excluding other diagnoses. Frequently ordered tests include routine blood tests to screen for infection and acute inflammation, plain radiographs to screen for fracture, and electrodiagnostics to screen for coexisting nerve injury and muscle fiber loss.

Differential Diagnosis

- Cellulitis
- Lymphedema
- Occult or stress fracture
- Acute synovitis
- Septic arthritis
- Septic tenosynovitis
- Scleroderma
- Plexitis, peripheral neuropathy
- Postherpetic neuralgia
- Peripheral vascular disease, arterial insufficiency
- Deep venous thrombosis, phlebitis
- Vasculitis

Treatment

The old saying that prevention is the best treatment may hold true for CRPS. Since 1999 [26], a series of studies have suggested that a 50-day regimen of daily vitamin C of at least 500 mg, started immediately after upper extremity trauma [27] or extremity surgery [28]—including foot, ankle, distal radius, hand, and wrist—may prevent the development of CRPS. This recommendation has been adopted into the 2010 American Academy of Orthopaedic Surgeons clinical guideline [29].

When prevention is ineffective, aggressive management of CRPS early in the course of disease may minimize long-term impairment. Pharmacotherapy, physical therapy, interventional pain procedures, and neuromodulation are common management options. The treatment of CRPS, in reality, is highly controversial because quality evidence is lacking.

Anti-inflammatory Medications

Inflammation is implicated at least in the early development of CRPS; nonsteroidal anti-inflammatory drugs are thus often employed as first-line agents. There is no definitive evidence supporting this practice. Topical formulations of dimethyl sulfoxide and *N*-acetylcysteine, both free radical scavengers thought to buffer the excess byproducts from inflammatory processes, are viable options to consider. Three randomized controlled studies (RCTs) found topical dimethyl sulfoxide 50% and *N*-acetylcysteine formulations somewhat effective at reducing pain and improving function in CRPS type I [30]. Corticosteroids have also been used to manage inflammation with mixed success. Two RCTs showed that oral prednisone may improve inflammatory symptoms [31]. Conversely, an RCT of intrathecal methylprednisolone was stopped prematurely because there was no benefit at midpoint analysis [32].

Neuropathic Medications

Antidepressants and anticonvulsants have been extensively studied, and there is strong evidence demonstrating their effectiveness in treating neuropathic pain. There is, however, not yet a clinical study of antidepressants specifically on the treatment of CRPS. One RCT [33] demonstrated some efficacy of gabapentin, yet no statistical significance

was found in another study [34]. The sedating side effects of both classes of medication can provide the added benefit of treating sleep disturbance.

Opioids and NMDA Receptor Antagonists

Opioids may be useful in the acute stages of CRPS for control of pain. Still, their use in chronic pain conditions remains controversial. Methadone may be considered for opioid-tolerant patients with severe neuropathic pain because of its *N*-methyl-D-aspartate (NMDA) receptor antagonist activity, which attenuates pain transmission through dorsal horn cells to the central nervous system.

Intravenous and 10% topical formulations of ketamine, a noncompetitive NMDA receptor antagonist, have been shown to significantly improve pain [35]. However, intravenous administration of ketamine warrants close monitoring, given a risk of psychedelic crisis, and repeated administrations have been associated with acute transaminitis [36]. Memantine is another noncompetitive NMDA receptor antagonist; its effectiveness when it is used alone has to be validated [37].

Bisphosphonates

Focal demineralization is a notable radiographic feature of CRPS, with a small contribution from disuse. Bisphosphonates are used to treat pathologic bone metabolism. Four RCTs have suggested that both oral and intravenous bisphosphonate formulations can improve pain in the acute inflammatory phase [32]. More research is necessary to determine the optimum formulation, dosage, and duration.

Novel Medications

A handful of novel medications were studied in the past decade. These studies are small and report only short-term outcomes, but they represent the continued effort of the medical community to find a better pharmacologic agent to treat CRPS. Tadalafil, a phosphodiesterase inhibitor aimed at reversal of the vasoconstrictive effect of CRPS, is one such medication under investigation and may provide pain reduction for patients with cold CRPS in the lower limbs [38]. Another promising RCT finds intravenous magnesium to improve pain and quality of life at 12 weeks after administration [39]. Last but not least is intravenous immune globulin [40], which significantly improved pain for three patients in an RCT with a sample size of 13.

Despite the early success described, many pharmacologic agents have proved ineffective. For more details on various medications that have been examined—including baclofen, lidocaine, and intranasal calcitonin—refer to a most comprehensive systematic review by Van Zundert et al [41].

Rehabilitation

Physical and Occupational Therapy

Existing RCTs find both physical and occupational therapies effective at improving pain and functional level. Relative to occupational therapy, physical therapy may provide quicker

pain reduction at a lower cost [42]. Studies are unable to detect greater benefit with varying of the frequency of physical therapy or use of specific aspects of therapy.

Complementary Therapies

Three large RCTs suggest that acupuncture, opposing needling, and electroacupuncture for post-stroke CRPS may improve pain, edema, and function [43]. Similar benefits were not apparent in a separate RCT studying post-traumatic CRPS [44]. Hyperbaric oxygen therapy may improve pain and edema on the basis of the result of one medium-sized RCT [45]. Last but not least, Qigong may provide long-term anxiety relief for chronic, refractory CRPS [46].

Mirror Therapy

Mirror therapy was first devised as a therapeutic tool to relieve pain in amputees from a poorly mobile or spasmodic phantom limb [47]. In mirror therapy, a patient moves both limbs—the affected limb as best as possible—while watching the reflection of the good limb (Fig. 99.1). Visual feedback from the reflection of the good limb—which looks like the affected limb moving normally—feeds into and improves the motor control loop of the affected limb, ideally improving movement of the affected limb [3]. One of us (V.S.R.) was the first to suggest that mirror therapy might be helpful in reflex sympathetic dystrophy/CRPS [2]. RCTs [48,49] and case reports [3,50,51] have since affirmed the benefit of mirror therapy in CRPS.

Mirror therapy can be useful by visual feedback, providing an “active assist” to promote and to improve movement. It can also reduce hyperesthesia and allodynia through progressive contact exercises of both limbs while the reflection of the unaffected limb is watched in the mirror.

In general, we urge patients to use the limb as much as is safely possible and to take back “ownership” of the limb (e.g., not to speak of the limb in the third person). The hope is that with early intervention for CRPS with mirror therapy and rehabilitation, pharmacologic, and other methods, it may be possible to prevent patients from progressing to the pachydermic, irreversible stage of CRPS.

FIGURE 99.1 The affected limb (left upper in this picture) is hidden behind the mirror in mirror therapy. The subject then follows the reflection of the healthy limb to mobilize both limbs simultaneously.

Procedures

Neuromodulation

Repetitive transcranial magnetic stimulation, in contrast to spinal cord stimulation, is approved by the Food and Drug Administration only for resistant major depressive disorder. It employs electromagnetic currents to stimulate cortical targets, which has previously been shown effective in chronic pain management. Two RTCs [52,53] for CRPS found repetitive transcranial magnetic stimulation to improve pain, possibly in the sensory discrimination and emotional dimensions of pain. An early attempt to use direct motor cortex electrical stimulation has had some success, but further study is needed [54].

Regional Procedures

Two types of regional sympathetic blocks are commonly used for CRPS: stellate ganglion block and lumbar sympathetic block. Stellate ganglion block, also known as cervicothoracic ganglion block, targets ganglion cells along the pharynx. It theoretically interrupts afferent painful signals from the upper limbs. Lumbar sympathetic block targets ganglion cells along the spine at L2-L4 levels and attempts to interrupt afferent painful signals from the lower limbs. The effectiveness of stellate ganglion and lumbar sympathetic blocks is variable in existing RCTs and on average shows only transient analgesic benefits [55]. Of note, compared with lumbar sympathetic block using bupivacaine alone, one small RCT found that the addition of botulinum toxin A may prolong the effects [56]. Longer lasting effects from stellate ganglion and lumbar sympathetic blocks may be achieved with radiofrequency lumbar sympathectomy and phenol neurolysis, but no further studies have been published [57].

Bier block can be used in the upper or lower limbs, and it involves use of a tourniquet to restrain blood flow into the affected limb while intravenous local anesthetic is administered. A small RCT in the 1980s found serial Bier blocks with guanethidine to be as effective as serial Bier block with lidocaine in management of upper limb reflex sympathetic dystrophy pain. However, recent RCTs did not find intravenous guanethidine, bupivacaine, or methylprednisolone effective for most patients [58].

Surgery

Spinal cord stimulation is approved by the Food and Drug Administration for treatment of refractory CRPS and neuropathic pain. Its action is attributed to central excitability suppression. Three medium-sized RCTs found the combination of spinal cord stimulation with physical therapy to be more effective than physical therapy alone for pain control in the short term, but this result does not appear to carry over in the long term [59]. Percutaneous cervicothoracic or lumbar sympathectomy is reserved for patients with severe CRPS, but effectiveness is questionable [60].

Potential Disease Complications

Functional disability from pain and hyperesthesia of CRPS is a significant concern. The most feared complication is progression of an affected limb to pachydermia, an irreversible

condition. Patients will then face severe, chronic pain. Limb contracture and muscle atrophy can result in loss of extremity function and potentially permanent disability.

Potential Treatment Complications

Adverse effects of pharmacotherapy vary according to the medication selected. For example, long courses of corticosteroids can produce significant endocrinologic disturbances and should be avoided; and nonsteroidal anti-inflammatory drugs have well-known adverse effects on the gastric, hepatic, and renal systems. Because polypharmacy may be necessary, care should be used in selection of interacting drugs that do not result in untoward side effects. Potential complications of stellate ganglion block are inadvertent arterial injection and seizures or recurrent laryngeal nerve injury. Perforation of the aorta, vena cava, or kidney can occur during lumbar sympathetic block. The most common complications of spinal cord stimulation include hardware failure, lead migration, infection, and failure to provide pain relief. Even for seemingly benign rehabilitation such as mirror therapy, one should be aware that patients can be at an increased risk for fall when they have increased mobility.

David A. Cassius, MD

Synonyms

Anterior chest wall syndrome
Costochondritis
Costosternal chondrodynia
Atypical chest pain

ICD-9 Code

733.6 Tietze disease; costochondral junction syndrome and costochondritis

ICD-Code

M94.0 Chondrocostal junction syndrome [Tietze], costochondritis

Definition

Costosternal syndrome is a frequent cause of anterior chest wall pain that affects the costosternal [1–6] or costochondral [2,4–7] joints. The pathogenesis of costosternal syndrome is still unknown [2,8]. Costosternal syndrome is considered an entity distinct from the rarely occurring Tietze syndrome [1–7,9] because it is a frequent cause of benign anterior chest wall pain. Also, as opposed to Tietze syndrome, it is not associated with local swelling of the involved costosternal or costochondral joints [1–7,9], and it usually occurs at multiple sites. The onset is usually after 40 years of age instead of at a young age as in Tietze syndrome, and it affects more women than men. A traumatic cause has been proposed [8], and currently it is suspected that repetitive overuse lesions of the costosternal joint and anterior chest [6,10] may be involved in the development of the degenerative changes found at the costosternal joint [11,12]. The costosternal joints may also be inflamed by osteoarthritis, rheumatoid arthritis, ankylosing spondylitis, Reiter syndrome, psoriatic arthritis, and the SAPHO (synovitis, acne,

pustulosis, hyperostosis, and osteitis) syndrome [3,7,12]. Infections of the costosternal joints are associated with tuberculosis, fungus (mycetoma, pulmonary aspergilloma, candidal costochondritis [13]), and syphilis as well as with viruses. The costosternal joints may also be the site of tumor invasion either from a primary malignant neoplasm, such as a chondrosarcoma or thymoma, or from a metastatic carcinoma, most commonly from the breast, kidney, thyroid, bronchus, lung, or prostate [12,14]. Chondromas and multiple exostoses are the most common benign tumors.

Costosternal syndromes may be a primary condition or secondary to these diseases. The condition occurs more frequently in women (a ratio of 2 to 3:1) and at an older age; two thirds of the patients are older than 40 years [1–4, 7,8]. The left side is more often involved. Costosternal joint disease is 1.69 times more frequent in patients who undergo median sternotomy than in normal controls of the same age [15].

Symptoms

The most common symptom in costosternal syndrome is pain of the anterior chest wall, usually localized at the precordium or at the left parasternal region [8,16]. Pain can radiate superiorly toward the left shoulder and left arm [8,16] and also to the neck, scapula, and anterior chest. Pain mainly develops after postural changes and maneuvers that place stress over the chest wall structures [16] rather than with physical efforts, such as those related to pain of cardiac origin [16]. Cardiac etiology for chest wall pain should be considered and ruled out [17]. Cough, deep breathing, and chest and scapular movements usually aggravate pain [5,11]. In contrast to Tietze syndrome, in which only one costal cartilage is involved in the majority of the patients, multiple sites are present in 90% of patients with costosternal syndromes [1,2,7–9]. The second to the fifth costal cartilages are most commonly affected [1–3,5,8,9]. Pain intensity may vary; it usually occurs at rest [12] and lasts for several weeks or months [8,16].

Physical Examination

Inspection of the patient suffering from costosternal syndrome reveals that the patient vigorously attempts to splint the joints by keeping the shoulders stiffly in neutral

position [12]. Differing from the Tietze syndrome, the costosternal syndrome has no visible spherical local swelling or any inflammatory signs at the costal cartilages [1,4,5,7,9]. Pain is reproduced by active protraction or retraction of the shoulder, deep inspiration, and elevation of the arm [12]. Palpation of the affected portions of the thoracic cage elicits local tenderness at multiple sites [9]. It may reproduce the patient's spontaneous pain complaint, including its radiation [9,18,19]. Some authors, however, have not found pain reproduction on palpation [4,5,16–19].

Several maneuvers have been found to be helpful in establishing the diagnosis [8,16]. Application of firm steady pressure to the following chest wall structures elicits the patient's pain complaint: the sternum, the left and right parasternal junctions, the intercostal spaces, the ribs, the inframammary area, and the pectoralis major and left upper trapezius muscles [8,16,18]. All of these can precipitate pain similar in quality and location to the spontaneous pain [16]. Another maneuver, called the horizontal flexion test (Fig. 100.1), consists of having the arm flexed across the anterior chest with the application of steady prolonged traction in a horizontal direction while, at the same time, the patient's head is rotated as far as possible toward the ipsilateral shoulder [2,6,8,10,16,18]. Another test, called the crowing rooster maneuver, consists of having the patient extend the neck as much as possible by looking toward the ceiling while the examiner, standing behind the patient, exerts traction on the posteriorly extended arms [2,8,16,18]. Associated myofascial pain syndrome of the intercostal, pectoralis major, pectoralis minor, and sternal muscles is a common feature of the syndrome. These muscles may be tender on palpation. Because this syndrome is usually confused with pain of cardiac [1,2,11,20,21], abdominal [2,9,16,22], or pulmonary [20] origin, a comprehensive history and physical examination are essential in all patients [8,18,19], including athletes [6,10].

Functional Limitations

Functional limitations may be due to the severe incapacitating chest pain [16]. Activities such as lifting, bathing, ironing, combing and brushing hair, and other activities of daily living can be very problematic. Patients will need to be at light duty

FIGURE 100.1 Horizontal flexion test for the diagnosis of costosternal syndrome.

for weeks and to avoid physical efforts of the upper limbs and trunk [14]. Even after a cardiac origin is ruled out for the chest discomfort, many patients do not return to full employment, recreation, or daily activities [23,24] and remain functionally impaired for years [24]. This functional impairment may occur even in patients with chest pain and normal angiographic studies [23,24] without a proven myocardial infarction. Many of these patients may have a costosternal syndrome. However, the continuing regular physician visits, medication consumption, emergency department visits, repeated hospitalizations, and repeated arteriographies may be contributing to the functional impairment.

Diagnostic Studies

The diagnosis of costosternal syndrome is usually a clinical diagnosis based on the detection of chest wall tenderness [11,16] that reproduces the spontaneous pain on physical examination [8,11,16,18,20,21]. Coronary heart disease [2,4,11,16,20,21], breast conditions [25], and pulmonary conditions [20,21] may be misdiagnosed as costosternal syndrome because of the anatomic proximity of the involved structures. Costosternal syndrome may also coexist with coronary artery disease [2,4,7,11,16,18] and other types of heart diseases [16]. The differentiation from anginal pain due to coronary heart disease may be judged by the pain characteristics. Typical anginal pain is substernal, provoked by exertion, and relieved by rest or nitroglycerin [20]. Atypical anginal pain has two of these symptoms, and nonanginal chest pain has only one of these symptoms [20]. Swap and Nagurney [21] described a low risk for acute coronary syndrome or acute myocardial infarction, with a likelihood ratio of 0.2 to 0.3, when chest pain is described as stabbing, pleuritic, or positional or is reproducible by palpation. The same authors also described a likelihood ratio of 2.3 to 4.7 for acute coronary syndrome when the chest pain radiates to one or both shoulders or arms or is precipitated by exertion [21]. In most patients with costosternal syndromes, the pain is usually localized in the anterior chest or parasternally at the level of the third or fourth intercostal space. As previously mentioned, it can also radiate superiorly toward the left shoulder and down the left arm. Patients experience pain at rest, and the pain can awaken them from sleep [8,16]. Chest pain characteristics, electrocardiographic abnormalities, or cardiac risk factors should be further evaluated by a cardiologist. Radionuclide cine-angiographic testing is a sensitive method to differentiate between costosternal syndromes and cardiac diseases [16].

Laboratory and imaging procedures are helpful in the diagnosis of the possible secondary causes of the costosternal syndromes and to rule out other causes of anterior chest pain [11,14].

Plain radiographs are indicated for patients who present with pain possibly emanating from the costosternal joints to rule out occult bone tumors, infections, and congenital defects. If trauma has occurred, costosternal syndrome may coexist with occult rib fractures or fractures of the sternum. These fractures may be missed on plain radiographs and can require radionuclide bone scanning for proper diagnosis. Increased uptake of radioactivity on bone scans is seen in most patients; however, it is not a specific test for making the diagnosis of costosternal syndrome [26].

Additional testing, including complete blood count, prostate-specific antigen level, sedimentation rate, and antinuclear antibody titer, may be indicated to rule out other diseases that may cause a costosternal syndrome, such as rheumatoid arthritis, ankylosing spondylitis, Reiter syndrome, and psoriatic arthritis. Magnetic resonance imaging of the joints is indicated if joint instability or occult mass is suspected. Diagnostic ultrasonography may also be indicated to investigate the presence of an occult mass.

Neuropathic pain caused by diabetic polyneuropathies and acute herpes zoster involving the chest wall may also be confused or coexist with costosternal syndrome [12].

A highly reliable test (and an effective differential diagnostic procedure that can confirm the diagnosis of costosternal syndrome) is the complete pain relief noted after an intercostal block at the posterior axillary line [8]. Patients with cardiac disease will have little or no effect on their pain because the nociceptive pathways from the heart are in the sympathetic afferents located in the paravertebral region. This test is both diagnostic and therapeutic.

In the secondary forms of costosternal syndromes, the underlying conditions should be addressed for good results [16].

Differential Diagnosis

- Angina pectoris
- Acute myocardial infarction
- Tietze syndrome
- Dislocation and fracture of the ribs, sternum, and clavicle
- Congenital sternoclavicular malformations
- Myofascial pain syndrome at the anterior chest wall:
 - sternal, pectoralis major, pectoralis minor, scalene,
 - sternocleidomastoid (sternal head), subclavius, and cervical
 - iliocostal muscles
- Tumors of the costal cartilages
- Costochondral dislocations
- Trauma and arthritis of the sternoclavicular joint
- Sternoclavicular hyperostosis
- Manubriosternal arthritis
- Trauma to the sternum
- Xiphoidalgia syndrome
- Diseases of the lung (pneumonia, lung abscess, atelectasis)
- Spontaneous pneumothorax
- Mediastinal emphysema
- Mediastinitis
- T1-12 radiculopathy (herpes zoster, postherpetic neuralgia)

Treatment

Initial

Initial treatment of the pain and functional disability associated with costosternal syndromes should include simple oral analgesics [2,18], such as acetaminophen and nonsteroidal anti-inflammatory drugs [12,27], alone or in combination with codeine [8] or tramadol. The use of an elastic rib belt may also provide symptomatic relief and help protect the costosternal joints from additional trauma [12]. Reassurance that the diagnosis is a non-life-threatening musculoskeletal pain syndrome can often by itself reduce the anxiety and fears and lead to symptomatic pain relief [2,6–9,11,16,27].

Rehabilitation

Physical modalities, such as local superficial heat for 20 minutes, two or three times a day, or ice for 10 to 15 minutes, three or four times a day, can be performed while symptoms are present [11,18]. Transcutaneous electrical nerve stimulation and electroacupuncture may be applied over the painful area. Gentle, pain-free range of motion exercises should be introduced as soon as tolerated. There is limited evidence to suggest that stretching exercises help for costochondritis pain [28]. Vigorous exercises should be avoided because they exacerbate the patient's symptoms. Perpetuating and aggravating factors [27], such as chronic coughing and bronchospasm, among others, should always be removed.

Procedures

For patients who do not respond to the initial or rehabilitation treatment modalities, a local anesthetic and steroid injection [5,6,9,11,12,25] can be performed as the next symptom control maneuver. Even in patients with coexisting true anginal pain, the relief of local chest pain is evident. Intra-articular injection of the costosternal joint (Fig. 100.2) is performed with the patient in the supine position [12]. The area of maximum tenderness can be infiltrated with a local anesthetic (2% lidocaine [7,25] or 0.25% preservative-free bupivacaine [12]) and methylprednisolone acetate [7,11,12,25] at the dosage of 10 mg per costosternal joint [25] by use of a 1½-inch, 25-gauge needle with strict aseptic technique [12]. The costosternal joints should be easily palpable as a slight bulging at the point where the rib attaches to the sternum [12]. An intercostal block at the posterior axillary line provides complete relief for 6 to 10 hours [8].

Surgery

Surgical procedures are rarely necessary [9]. Costosternal or sternoclavicular arthrodesis may be performed if conservative measures fail to provide satisfactory results.

FIGURE 100.2 Schematic representation of the injection site at the second costosternal junction.

Potential Disease Complications

Costosternal syndromes are of benign origin, and complications rarely develop. They are self-limited [9], and spontaneous recovery usually occurs after 1 year in the majority of the cases [4]. Pain exacerbation due to physical activities and overload is usually followed by spontaneous recovery. However, as mentioned earlier, because of the many pathologic processes that may mimic the pain of costosternal syndrome, the clinician should always be careful to rule out underlying cardiac, lung, breast, and mediastinum diseases.

Potential Treatment Complications

The systemic complications of analgesics such as nonsteroidal anti-inflammatory drugs are well known and most commonly affect the gastric, hepatic, and renal systems. Local steroid combined with local anesthetic injections may cause pneumothorax if the needle is placed too laterally or deeply and invades the pleural space [12]. Cardiac tamponade as well as trauma to the contents of the mediastinum, although rare, can occur. This complication can be greatly decreased if the clinician pays close attention to accurate needle placement [12] or performs the injection with ultrasonographic guidance. Transient marked hypophosphatemia has been documented 8 hours after an intra-articular glucocorticoid injection in a patient with chronic costochondritis [29]. In this patient, hypophosphatemia was clinically characterized by limb paresthesia and weakness, followed by dysarthria [29]. All of these symptoms resolved within hours, even before the hypophosphatemia resolved [29]. Iatrogenic infections can also occur if strict aseptic techniques are not followed [12].

Fibromyalgia

Melissa Colbert, MD

Joanne Borg-Stein, MD

Synonym

Fibrositis

ICD-9 Code

729.1 Myalgia and myositis, unspecified

ICD-10 Codes

M79.1 Myalgia

M60.9 Myositis, unspecified

Definition

Fibromyalgia is a syndrome defined by chronic widespread pain of at least 3 months' duration. It is a multisystem illness associated with neuropsychological symptoms including fatigue, stiffness, unrefreshing sleep, cognitive dysfunction, anxiety, and depression. The majority of patients are women, for whom fibromyalgia is six times more common than in men [1]. The prevalence of the condition increases with age and is greater than 7% in women older than 60 years [2].

A discrete etiology of fibromyalgia has not been identified. Available evidence implicates sensitization of the central and peripheral nervous systems as key in maintaining pain and other core symptoms of fibromyalgia [3–6]. There may be a role for genetics, as individuals with certain genotypes are more likely to develop chronic pain and an overall increased sensitivity to pain during their lifetimes. These genes include catecholamine methyltransferase, sodium and potassium channels, and a number of others. Environmental factors, such as physical or emotional trauma, and infection (e.g., Epstein-Barr virus, Lyme disease, parvovirus), may interact with genetic factors to facilitate the development of fibromyalgia [6].

According to the 2010 American College of Rheumatology preliminary diagnostic criteria for fibromyalgia and measurement of symptom severity, a patient must have a widespread

pain index score of at least 7 and a symptom severity scale score of at least 5 or a widespread pain index score of at least 3 and a symptom severity scale score of at least 9. The scoring is based on number and severity of somatic symptoms. In addition, symptoms must be present at a similar level for at least 3 months, and the patient must not have another disorder that would otherwise explain the pain (Table 101.1). These criteria do not include a tender point examination, as previously described by the 1990 American College of Rheumatology diagnostic criteria [7].

Symptoms

Fibromyalgia is characterized by widespread and long-lasting pain (>3 months) located above and below the waist, on both sides of the body. A series of other symptoms are frequently reported by patients. These include marked fatigue, stiffness, sleep disorders, cognitive disturbances (e.g., decreased comprehension, memory problems), anxiety, depression, temporomandibular joint syndrome, paresthesias, headache, genitourinary manifestations (e.g., pelvic or bladder pain), irritable bowel syndrome, and orthostatic intolerance [4].

Physical Examination

The findings of the general medical examination, including thorough joint inspection, should be normal. Blood pressure recording for orthostatic hypotension is performed. Mood and affect are noted.

The neurologic examination findings should also be largely normal but may demonstrate slight sensory or motor abnormalities [8]. By conducting a comprehensive neurologic and musculoskeletal examination, one may rule out superimposed pain generators, such as bursitis, tendinitis, radiculopathy, and myofascial trigger points.

Functional Limitations

Patients are limited in their daily activities and exercise tolerance by both pain and fatigue. Patients also report cognitive dysfunction with difficulty in concentration, organization, and motivation. This has been termed “fibro fog.” Approximately 25% of patients with fibromyalgia report themselves disabled and are collecting some form of disability payment. Individuals are more likely to become disabled if they report higher pain scores, work at a job that requires

Table 101.1 Widespread Pain Index and Symptom Severity Scale Scores**Widespread Pain Index (score 0-19, 1 point for each location)***Has the patient had pain in any of the following areas in the last week?*

Shoulder girdle (left)	Neck	Upper arm (left)	Upper leg (left)	Hip (left)
Shoulder girdle (right)	Upper back	Upper arm (right)	Upper leg (right)	Hip (right)
Jaw (left)	Chest	Lower arm (left)	Lower leg (left)	Lower back
Jaw (right)	Abdomen	Lower arm (right)	Lower leg (right)	

Symptom Severity Scale (score 0-12, total of specific symptoms plus general severity)*Specific symptoms: How severe have the following symptoms been during the last week?*

(0=no problem, 1=slight/mild/intermittent, 2=moderate/frequent, 3=severe/pervasive/continuous)

- Fatigue
- Waking unrefreshed
- Cognitive symptoms

Number of general somatic symptoms (0=none, 1=few, 2=moderate, 3=many)

A patient must have a widespread pain index score of at least 7 and a symptom severity scale score of at least 5 or a widespread pain index score of at least 3 and a symptom severity scale score of at least 9.

Data from Wolfe F, Clauw DJ, Fitzcharles M, et al. The American College of Rheumatology preliminary diagnostic criteria for fibromyalgia and measurement of symptom severity. *Arthritis Care Res* 2010;62:600-610.

heavy physical labor, have poor coping strategies and feel helpless, or are involved in litigation [9-11].

Diagnostic Studies

Fibromyalgia is a clinical diagnosis. For other conditions to be excluded, basic laboratory tests may be appropriate, such as complete blood count, erythrocyte sedimentation rate, thyroid-stimulating hormone concentration, liver transaminases, and creatine kinase activity. Primary sleep disorders may need to be identified by sleep studies. Radiography or magnetic resonance imaging may be indicated if osteoarthritis, radiculopathy, spinal stenosis, or intrinsic joint disease is suspected.

Electrodiagnostic studies may be useful to rule out an entrapment neuropathy or radiculopathy. The results of these studies will be normal in a patient with fibromyalgia but may be abnormal in the setting of a neuropathy.

Differential Diagnosis

Thyroid myopathy
Metabolic myopathy
Mood disturbances
Somatoform pain disorders
Rheumatic disease
Neuropathies

Treatment

Initial

Initial treatment includes education of the patient, pharmacologic treatment, gentle exercise, and relaxation training. A stepwise, multidisciplinary approach to fibromyalgia management is recommended. The first step is to confirm the diagnosis, to explain the condition, and to treat any comorbid illness, such as mood or sleep disturbance (see later). Education of the patient, which itself has been shown

to have a therapeutic effect, includes individual and group classes that review the symptoms of fibromyalgia and emphasize the importance of adhering to a treatment program. It reassures the patient as to the generally benign course and outlines the treatment path [12-16].

The second step is to use pharmacologic and nonpharmacologic therapy, with emphasis on an individualized treatment plan. Trials with selective serotonin reuptake inhibitors, serotonin and norepinephrine reuptake inhibitors, or low-dose tricyclic antidepressants should be considered. One may use a combination medication trial or anticonvulsant [15]. The patient should begin a cardiovascular exercise program and be referred for cognitive-behavioral therapy or combine that with exercise.

The third step is specialty referral to rheumatology, physiatry, psychiatry, or pain management.

Pharmacologic management aims to normalize sleep patterns, to reduce fatigue, and to diminish pain. A low-dose tricyclic antidepressant at bedtime (e.g., amitriptyline, 10 to 25 mg) with a low-dose selective serotonin reuptake inhibitor (e.g., fluoxetine, 20 mg every morning) is an excellent and cost-effective combination. The combination works better than either medication alone. Cyclobenzaprine, which relies on a mechanism of action similar to that of tricyclic antidepressants, may also be used [17]. Studies demonstrate that the serotonin-norepinephrine reuptake inhibitors duloxetine and milnacipran are beneficial for patients with fibromyalgia, having the greatest impact on important symptoms such as pain and sleep [6,15,18].

Pain may be relieved with nonsteroidal anti-inflammatory drugs in combination with antidepressants or anticonvulsants, such as gabapentin or pregabalin. Pregabalin reduces pain in patients with fibromyalgia at doses of 300 to 450 mg/day in three divided doses, starting with 50 mg at bedtime and titrating up as tolerated. Opioids are rarely necessary. Tramadol, a μ opiate agonist with serotonergic and noradrenergic effects, may be used alone or in combination with acetaminophen [6,16]. Adjunctive nonpharmacologic pain control methods include acupuncture, massage, aqua therapy, yoga, Thai Chi, and biofeedback [6,19,20].

Rehabilitation

Physical therapy is used to educate the patient in a stretching, gentle strengthening, and cardiovascular fitness program. The aerobic exercise prescription includes low-impact interventions, such as walking and swimming, and should recommend low-intensity exercise that gradually increases to moderate intensity [1]. This can improve fitness and function and decrease pain. Occupational therapy is incorporated to review ergonomics of daily activities, and activities of daily living are reviewed at the work site. Task simplification, pacing, and maximization of function are emphasized [12,21–24].

Mental health professionals can be helpful in the rehabilitative phase to educate the patients in a mind-body stress reduction program, which may include cognitive-behavioral therapy, relaxation, and biofeedback. This provides the patient with positive coping strategies for living with chronic pain [15,25,26]. Associated depression and anxiety often need psychopharmacologic treatment as well.

Procedures

Trigger Point Injections

Myofascial trigger points may be injected with 1% lidocaine to decrease local pain and to increase pain thresholds [27]. Patients with recalcitrant chronic myofascial pain may respond to injections with botulinum toxin [28].

If patients have concurrent bursitis, tendinitis, or nerve entrapment, therapeutic injections may be performed to treat these specific diagnoses.

Acupuncture

Acupuncture can be used for treatment of pain and fatigue. Preliminary studies suggest that the benefit may last up to several months. Treatment two times per week for at least six visits appears necessary. Improvement lasts at least 1 month but is likely to wane over time. The optimal number and frequency of acupuncture treatments have not been determined [2,29–31].

Surgery

There is no surgery indicated for fibromyalgia.

Potential Disease Complications

Failure to make the diagnosis early may lead to delay in treatment, deconditioning, and expensive unnecessary medical testing and procedures. Chronic, intractable pain may occur despite treatment.

Potential Treatment Complications

Tricyclic antidepressant medications can be associated with anticholinergic side effects, such as urinary retention, sedation, constipation, and weight gain. Pregabalin may lead to dizziness, peripheral edema, and weight gain. Selective serotonin reuptake inhibitor medications may be associated with sexual dysfunction, gastrointestinal intolerance, and anorexia. Overly aggressive exercise programs may transiently increase pain in some patients. Injections may result in local pain,

ecchymosis, intravascular injection, or pneumothorax if they are improperly executed. There is an increased risk of bleeding with use of nonsteroidal anti-inflammatory drugs and selective serotonin reuptake inhibitors. For patients taking high-dose serotonin reuptake inhibitors, consider avoidance or minimal use of nonsteroidal anti-inflammatory drugs [32]. There is also emerging concern for cardiovascular risks associated with nonsteroidal anti-inflammatory drugs [33]. The threshold for seizures is lowered by tramadol. In addition, the risk for seizure is enhanced by the concomitant use of tramadol with selective serotonin reuptake inhibitors [34].

Definition

The three major primary headache disorders are migraine, cluster, and tension-type headache [1]. Although all three syndromes are characterized by chronic, recurrent, and potentially disabling headaches, specific diagnosis is important because of differing natural history and treatment.

Headache disorders are classified according to criteria outlined in the International Classification of Headache Disorders, originally developed by the International Headache Society in 1988 and revised in 2004 [1]. The criteria are available online (www.ihs-headache.org) and are due to be revised soon [2]. However, changes to criteria for the three primary headache disorders are expected to be minor. Diagnosis of all but a few rare migraine subtypes remains clinical, based on the patient's history and an examination that rules out secondary causes of headache (not covered in this chapter). The International Classification of Headache Disorders criteria were developed for research purposes and lack sensitivity when they are used in the clinical setting. Both migraine and tension-type headaches are more common in women than in men; cluster headache is generally a male disorder. Peak prevalence of migraine occurs during midlife, when it affects almost a quarter of all women and roughly 10% of men [3]. Recurrent headaches are not rare in children, but accurate diagnosis can be difficult because headache presentation in children varies from that in adults, and children may have difficulty describing the headache characteristics needed for a diagnosis to be made [4].

Migraine

Migraine is subclassified as migraine without aura (Table 102.1) and migraine with aura (Table 102.2). About 20% of patients have aura, usually preceding the headache, which consists of focal neurologic signs or symptoms that begin gradually and fade away within 30 to 60 minutes as the headache begins. The most common type of aura involves visual disturbances, typically an enlarging scotoma, but patients can also see shapes such as stars, zigzag lines, or other visual distortions, including field cuts and photopsias. Sensory or motor problems occur far less frequently. Blurry vision is usually not considered a part of aura. Migraine can also be classified as episodic or chronic (15 or more migraine headache days per month). Three gene mutations have been

Table 102.1 Diagnostic Criteria for Migraine without Aura

- A. At least five attacks fulfilling B-D.
- B. Headache attacks lasting 4-72 hours (untreated or unsuccessfully treated).
- C. Headache has at least two of the following characteristics:
 - 1. Unilateral location
 - 2. Pulsating quality
 - 3. Moderate or severe intensity (inhibits or prohibits daily activities)
 - 4. Aggravated by or causes avoidance of routine physical activity
- D. During headache at least one of the following:
 - 1. Nausea and/or vomiting
 - 2. Photophobia and phonophobia
- E. At least one of the following:
 - 1. History, physical, and neurologic examinations do not suggest one of the disorders listed in groups 5-11.
 - 2. History and/or physical and/or neurologic examinations do suggest such disorder, but it is ruled out by appropriate investigations.
 - 3. Such disorder is present, but migraine attacks do not occur for the first time in close temporal relation to the disorder.

From Headache Classification Subcommittee of the International Headache Society. The International Classification of Headache Disorders: 2nd edition. Cephalalgia 2004;24(Suppl 1):1-160.

Table 102.2 Diagnostic Criteria for Migraine with Aura

- A. At least two attacks fulfilling B.
- B. At least three of the following four characteristics:
 - 1. One or more fully reversible aura symptoms indicating focal cerebral cortical and/or brainstem dysfunction.
 - 2. At least one aura symptom develops gradually over more than 4 minutes, or two or more symptoms occur in succession.
 - 3. No aura symptom lasts more than 60 minutes. If more than one aura symptom is present, accepted duration is proportionally increased.
 - 4. Headache follows aura with a free interval of less than 60 minutes. (It may also begin before or simultaneously with the aura.)
- C. At least one of the following:
 - 1. History, physical, and neurologic examinations do not suggest one of the disorders listed in groups 5-11.
 - 2. History and/or physical and/or neurologic examinations do suggest such disorder, but it is ruled out by appropriate investigations.
 - 3. Such disorder is present, but migraine attacks do not occur for the first time in close temporal relation to the disorder.

From Headache Classification Subcommittee of the International Headache Society. The International Classification of Headache Disorders: 2nd edition. Cephalalgia 2004;24(Suppl 1):1-160.

identified that are associated with a particular subtype of migraine with aura known as familial hemiplegic migraine. These genes influence the stability of neuronal cell membranes [5,6]. Some patients are able to identify triggers for their headache, including exertion, certain foods, and hormonal influences.

Cluster

Cluster headaches are strictly unilateral headaches that are far more common in men than in women, but the

prevalence in the general population overall is approximately 0.1% [7]. The pain is sharp and steady, in contrast to the throbbing pain of migraine, and localized to the orbital area. Diagnostic criteria require the presence of at least one autonomic sign or symptom during the headache, such as ipsilateral conjunctival injection, lacrimation, rhinorrhea, ptosis, or miosis.

Cluster headache is so called because the headaches occur regularly in most cases, from one to eight times a day, during a period of 2 weeks to 3 months that is referred to as a cluster episode. The headaches then completely remit for months or years. In chronic cluster headache, there are no headache-free periods or remissions, or they are less than 2 weeks in duration [8]. Patients with cluster headache usually describe alcohol intolerance during the cluster episode and generally note intense restlessness during the headache.

Tension Type

Tension-type headaches can vary in length from 30 minutes to 7 days. They are typically bilateral, moderate in intensity, and described as a pressing, squeezing sensation that is not affected by physical activity. Associated symptoms, such as nausea, vomiting, photophobia, and phonophobia, are generally not present or are mild. Tension-type headache is subclassified as infrequent episodic if it occurs less than 1 day per month, frequent episodic if it occurs from 1 day to 14 days per month, and chronic with attacks occurring 15 days or more per month for at least 6 months [1]. Patients with tension-type headache typically do not spontaneously report symptoms other than headache. A diagnosis of migraine should be reexamined if multiple associated symptoms are reported, like nausea and photophobia, which are thought to be a part of the sympathetic activation that occurs with migraines.

Symptoms

In addition to the aforementioned symptoms that are required for diagnosis, many patients with migraine report prodromal symptoms: yawning; neck and shoulder muscle discomfort; excessive salivation; and changes in appetite, mood, sleep, gastrointestinal function, and urination. Some of these can start days before the actual headache. Postdromal symptoms in migraine include fatigue, exercise intolerance, and neck and shoulder muscle discomfort. If headaches progress untreated, 80% of patients eventually develop allodynia, defined as pain in response to stimuli that normally are nonpainful. Once allodynia develops, treatment may be less successful [9].

Physical Examination

The primary headache disorders are diagnosed by history. The major purpose of physical and neurologic examination is to rule out the presence of secondary headache disorders. Accordingly, the most important parts of the physical examination are funduscopic examination to exclude papilledema and neurologic examination to exclude focal deficits that might suggest a malignant neoplasm, vascular causes like stroke or hemorrhage, collagen vascular disease, or infectious cause of headaches, among others.

Interictally, the physical and neurologic examination findings will be normal in primary headache disorders, or if another disorder is identified, it must not be causally related to the primary headache. Subtle cerebellar signs, such as dysmetria and balance abnormalities, have been detected in migraineurs compared with normal controls, but these are generally not detectable in a typical examination [10].

If the patient is examined during a headache attack, the following points should be specifically noted.

- Patients experiencing migraine lie quietly, avoid movement, and may appear pale and diaphoretic. They typically display marked photophobia and phonophobia and may be vomiting.
- Patients experiencing cluster headache are physically restless, in contrast to migraine sufferers.
- Head banging and agitation are common [11]. Autonomic signs should be documented to confirm the diagnosis. Between attacks, persistent ptosis and conjunctival injection may occasionally be seen.
- Patients experiencing tension-type headache may appear uncomfortable but generally are not incapacitated.
- Neck, shoulder, and jaw tightness is common in patients with prolonged episodes of all primary headache types and does not necessarily represent the underlying cause of the headache. In most cases, these complaints will improve with appropriate treatment of the headache and do not need to be treated separately. There is no evidence that patients with tension-type headache have abnormally elevated muscle tension. In fact, electromyographic findings do not have diagnostic or treatment implications in migraine or tension-type headache [12]. Although biofeedback-assisted muscle relaxation is clearly of benefit in migraine and tension-type headache, it may exert its effect through mechanisms other than muscle relaxation.

Functional Limitations

Quality of life surveys and other data suggest that patients with primary headache disorders are more functionally impaired than is commonly appreciated [13]. Obviously, acute attacks of migraine and cluster headache prohibit function and generally require bed rest if untreated. Visual aura can render driving or other hazardous activities dangerous or even impossible. Tension-type headache does not generally prohibit activities but may inhibit them. Patients commonly report feeling that they are not functioning at “full capacity.” In many cases, severely affected patients report that fear and anxiety about possible attacks lead them to avoid, to cancel, or to decline work, social, and academic opportunities. Depression is a common comorbidity with poorly controlled headaches and also may lead to impaired function. The functional limitations imposed on many patients by nonspecific sedative treatments for migraine or by prophylactic treatments, which can cause fatigue, exercise intolerance, weight gain, and depression, are also underappreciated.

Diagnostic Studies

The primary headache disorders are clinical diagnoses, with the exception of the rare hemiplegic migraine syndromes. In general, imaging studies or laboratory tests are done to rule

out secondary headache disorders, not to rule in primary disorders. With the exception of genetic testing for genes associated with familial hemiplegic migraine, there are currently no laboratory, genetic, or imaging markers that confirm a diagnosis of ordinary migraine with or without aura in individual patients. Biomarkers do exist that can distinguish subgroups of migraineurs, like those with hemiplegic migraine, from one another or from normal controls [14]. Some of the red flags to look out for that signal a secondary headache include change in pattern of headaches, headaches on awakening, any associated neurologic deficits, and headaches with onset in older age.

Differential Diagnosis

MIGRAINE

Seizure disorder
Sinus infection
Early subarachnoid hemorrhage
Collagen vascular disorders
Meningitis
Space-occupying central nervous system lesion
Post-traumatic headache

CLUSTER

Trigeminal neuralgia
Cavernous sinus thrombosis
Central nervous system or ear, nose, or throat tumor
Orbital cellulitis or fracture
Subarachnoid hemorrhage
Dental abscess

TENSION TYPE

Mild or forme fruste migraine attack
Temporomandibular disorder
Space-occupying central nervous system lesion

Treatment

Initial

Headache treatment consists of nonpharmacologic measures, lifestyle changes, and abortive treatment of acute attacks [15]. Another option, prophylactic treatment, in which daily medication is given to decrease the frequency and severity of headache episodes, is reserved for patients who do not obtain acceptable relief from abortive therapy or have more than two headache attacks a week. Although there is some overlap in treatment options among the various headache disorders, there are also important differences. In particular, cluster headache is often erroneously treated for years with migraine medication, to little or no avail [16].

Migraine

Lifestyle modification includes regular and adequate sleep and hydration, avoidance of excess caffeine, avoidance of missed meals, avoidance of alcohol (not a trigger for all migraine patients), and regular aerobic exercise. Although it is commonly advised, there is no scientific evidence that avoidance of chocolate, dairy products, or the myriad other dietary factors anecdotally implicated in migraine is helpful

for the majority of patients with migraine. In the absence of good scientific evidence, it does not seem wise to promote food anxieties.

Nonpharmacologic treatment includes therapies such as cognitive-behavioral therapy, biofeedback-assisted relaxation, physical therapy, and acupuncture (although there is weak evidence of acupuncture's benefit). Physical therapy has *not* been shown to be useful in a trial that compared physical therapy and medication for migraine with medication alone [17]. If physical therapy is used, it should be short term and focus on development of an aerobic or other exercise program rather than on passive therapeutic modalities. One study did suggest that aerobic exercise 40 minutes three times a week is as effective as topiramate and relaxation training [18]. Biofeedback can also provide long-term benefits for patients with migraine.

Abortive therapy consists of nonsteroidal anti-inflammatory drugs, with or without caffeine; isometheptene compounds; opioids, with or without aspirin or acetaminophen; barbiturate-containing compounds (e.g., Fiorinal, Fioricet, Esgic, Phrenilin); ergots (e.g., Cafergot, Wigraine, D.H.E. 45); and triptans (sumatriptan, rizatriptan, zolmitriptan, naratriptan, frovatriptan, eletriptan, almotriptan). Keeping headache diaries should be emphasized for better monitoring.

Prophylactic therapy consists of nonsteroidal anti-inflammatory drugs; topiramate; beta blockers, especially propranolol (except those with sympathomimetic activity); calcium channel antagonists; tricyclic antidepressants, especially amitriptyline; riboflavin (vitamin B₂); sodium valproate; and selective serotonin reuptake inhibitors (weak evidence of benefit). Recently released preventive migraine treatment guidelines from the American Academy of Neurology and the American Headache Society assign sodium valproate, propranolol, metoprolol, and topiramate to the top level of treatment choices on the basis of an assessment of efficacy alone [19].

Cluster

Lifestyle modification includes alcohol avoidance and stress reduction.

Nonpharmacologic therapy employs 100% oxygen; 10 to 12 liters at headache onset by non-rebreather mask for 10 to 15 minutes aborts headache in 80% of patients.

Abortive therapy generally must be parenteral because headaches are short and onset is sudden. Options include oxygen, as previously described; dihydroergotamine, 1 mg subcutaneously; sumatriptan, 6 mg subcutaneously; and parenteral opioids.

Prophylactic therapy includes lithium carbonate, steroids (duration and dose must be limited to avoid side effects; principally used while results are awaited from other prophylactic medications), verapamil (high doses required), sodium valproate (benefit unclear), and topiramate (benefit unclear).

Tension Type

Lifestyle modification includes regular and adequate sleep and aerobic exercise.

Nonpharmacologic therapy includes biofeedback (thermal or electromyographic). Physical therapy focuses on stretching and strengthening exercise rather than on passive modalities.

Acute therapy consists of nonsteroidal anti-inflammatory drugs and isometheptene combinations. Potentially sedative or habit-forming opioid or barbiturate-containing compounds should generally be avoided.

Prophylactic therapy consists of nonsteroidal anti-inflammatory drugs, tricyclic antidepressants, and sodium valproate.

Rehabilitation

Patients whose headaches are refractory to currently available treatments suffer significant disability. Secondary depression and medication overuse may develop, along with family dysfunction and poor work performance. The development of chronic pain syndrome (in which patients develop disability out of proportion to the underlying disease, with associated behavioral abnormalities) requires interdisciplinary treatment for best results. The treatment philosophy, which must be accepted by the patient and family, shifts from cure to management. Medication reduction, increased "up" time and regular physical exercise, involvement in hobbies or return to work, and psychological intervention all help return the patient to some semblance of normal living, despite the persistence of headache [20]. Inpatient rehabilitation may be necessary for patients with severe medication overuse, who require special tapering from narcotic or barbiturate drugs, or who have associated medical or psychiatric morbidity that precludes outpatient treatment. Only a handful of such programs exist in the United States because of the reluctance of insurance companies to compensate for them.

Procedures

Onabotulinum toxin type A injections into the pericranial musculature received approval by the Food and Drug Administration for treatment of chronic migraines in 2010. Pooled data from two randomized controlled trials showed that it was useful in patients with chronic migraine (15 or more headache days per month), although its use is limited by cost and insurance coverage problems [21,22]. Episodic or chronic headaches associated with significant pericranial muscle spasm or pain may benefit from localized trigger point injections or occipital nerve blocks [23,24]. Trigger point injections for headache are small-volume injections into one or more tender or painful muscles in the head or neck. The injection may be of a local anesthetic alone, such as 0.5 to 1.5 mL of 0.25% or 0.5% bupivacaine, or in combination with a steroid, such as 1.5 mL of 0.5% bupivacaine and 0.25 mL of methylprednisolone sodium succinate (Solu-Medrol) 20 mg/mL. Trigger point injections may be repeated at 2-month intervals as needed [23]. Greater occipital nerve block is performed by injection of a combination of local anesthetic and steroid 2 cm lateral to the occipital protuberance; a common dose is 2 mL of 2% lidocaine with 5 mg of triamcinolone [24].

Surgery

Ablative surgical procedures on the fifth cranial nerve (radiofrequency, cryotherapy, and alcohol techniques) are employed in cases of refractory cluster headache. Implanted sphenopalatine ganglion stimulators are a promising but

investigational approach for some patients. Some women with migraine contemplate oophorectomy, in the belief that elimination of hormonal cycling may eliminate migraine. In fact, abrupt surgical menopause seems to worsen, not improve, migraine, and this procedure should be discouraged. There is no clear evidence on whether closure of patent foramen ovale is helpful in the treatment of migraine with aura. Occipital nerve stimulators are under investigation for treatment of refractory migraine. Other surgical approaches, such as operations to release peripheral “trigger sites,” have scanty evidence of benefit and in the absence of larger trials should not be recommended.

Potential Disease Complications

Inadequately managed headaches can directly or indirectly lead to depression, suicide, addiction and dependence syndromes, unemployment, divorce, and poor progress in school and the workplace. Emerging evidence indicates structural brain changes in some patients with long-duration, poorly controlled migraine attacks [25]. These include iron deposition in areas of the brainstem, white matter lesions, and reduction in gray matter volume. Migraine is a risk factor for ischemic stroke and may also increase the risk of coronary heart disease. Women with migraine are more likely to develop preeclampsia and to suffer postpartum stroke [26].

Potential Treatment Complications

Possible complications from injections include an allergic reaction to the medication and infection. Potential complications from cluster headache surgery include anesthesia dolorosa, dry eye, and facial anesthesia or weakness. Multiple reactions to oral medications are possible, and the clinician should be aware of the side effect profile for any medications prescribed. A 2006 Food and Drug Administration advisory warns about possible serotonin syndrome with concomitant use of selective serotonin reuptake inhibitors or serotonin-norepinephrine reuptake inhibitors and triptans. From a clinical perspective, the risk appears very low, but it is worth considering in patients using both medications who have unusual side effects. Most experts do not think, however, that the combination is absolutely contraindicated. Overuse of symptomatic medications for headache may lead to medication overuse headache syndromes that can be difficult to treat.

353.8 Intercostal neuralgia
954.8 Intercostal nerve injury

ICD-10 Codes

G58.0 Intercostal neuralgia
G58.0 Intercostal neuropathy

Definition

Intercostal neuralgia is pain in the thoracic region emanating from an intercostal nerve. The pain is typically a sharp, shooting, or burning pain radiating around the chest wall. It can be accompanied by altered sensitivity to touch, such as allodynia or an area of hyperalgesia. Intercostal neuralgia occurs commonly after thoracotomy [1–4]. It can also be seen in elderly debilitated patients without a known precipitating event [5]. Other causes include rib trauma, very rarely benign periosteal lipoma [6], and pregnancy [7].

Intercostal nerves are peripheral nerves that run along with the vascular bundle on the inferior surface of each rib (Fig. 103.1). Intercostal nerves are derived from the ventral rami of the first through twelfth thoracic nerves (Fig. 103.2), with the first, second, third, and twelfth being atypical on the basis of anatomic differences. Only 17% of intercostal nerves were found in the classic subcostal position in one study [8]. In Hardy's study, a midcostal location was the most prevalent at 73%; an additional 10% were supracostal. The intercostal nerve gives off four main branches as it travels anteriorly: gray rami communicantes, posterior

cutaneous branch, lateral cutaneous division, and anterior cutaneous division.

Symptoms

Chest pain is the cardinal symptom. Because intercostal neuralgia involves a peripheral nerve, the pain is neuropathic rather than nociceptive. Neuropathic pain is often unrelenting, shooting, burning, and deep. The International Association for the Study of Pain defines neuropathic pain as "pain initiated or caused by a primary lesion or dysfunction in the nervous system." [9] Neuropathic pain is characterized by three symptoms: dysesthesia, paroxysmal pain, and allodynia [10]. Dysesthetic pain is an abnormal sensation described as unpleasant. Patients commonly use terms such as aching, cramping, pressure, and heat to describe a dysesthetic pain [11]. Paroxysmal pain is pain that comes in waves and is often described as lancinating or electric. Allodynia is the abnormal perception of pain after a normally nonpainful mechanical or thermal stimulus [11]. Patients with allodynia may respond to light touch with an exaggerated pain response or report a sensation of heat when a cold stimulus is applied. Intercostal neuralgia pain is unilateral. It is common (up to 81% of patients) after thoracotomy for coronary artery bypass grafting to the internal thoracic artery and after thoracotomy for tumor excision [3,4]. During thoracotomy (either open or video-assisted thoracoscopic surgery), the intercostal nerve may be directly injured during rib resection, compressed by a retractor, or later entrapped by a healing rib fracture. Intercostal neuralgia may follow other forms of chest trauma. It may mimic the pain of shingles (herpes zoster) but without the rash and can occur without significant trauma in the elderly.

The mechanism of neuropathic pain may be due to ectopic signals from neural "sprouts" after axonal injury. This new nerve growth may become a pain generator, especially if it becomes entrapped in scar tissue, forming a neuroma. Another mechanism may be compression or disruption of the nervi nervorum afferents in the connective tissue covering, producing a peripheral neuropathic pain.

Physical Examination

Much of the physical examination in intercostal neuralgia is done to exclude other sources of pain. First, it is

FIGURE 103.1 Intercostal nerve location. The intercostal nerve (N) runs along the inferior rib with the artery (A) and vein (V). (From Chung J. Thoracic pain. In Sinatra RS, Hord A, Ginsberg C, Preble L, eds. *Acute Pain*. St. Louis, Mosby, 1992.)

FIGURE 103.2 Intercostal nerves are derived from the ventral rami of the first through twelfth thoracic nerves. (From Saberski LR. Cryoneurolysis in clinical practice. In Waldman S, ed. *Interventional Pain Management*, 2nd ed. Philadelphia, WB Saunders, 2001.)

important to exclude cardiac and other visceral sources of chest pain (Table 103.1). Although point tenderness is uncommon during myocardial infarction, the presence of point tenderness does not exclude significant cardiac

disease. In intercostal neuralgia, there are no constitutional signs, such as fever, dyspnea, diaphoresis, or shortness of breath. Cardiopulmonary examination findings should be normal or stable if prior cardiovascular or pulmonary disease exists.

Intercostal neuralgia is common after thoracotomy [1–3]. However, chest pain that recurs after a pain-free period following a thoracotomy for tumor resection is likely (90%) to be due to tumor recurrence. On the other hand, pain that persists for months or years after thoracotomy is most likely (70%) intercostal neuralgia [12].

Once the chest pain has been determined to be neuromusculoskeletal and nonvisceral, the task becomes one of differentiation of intercostal neuralgia from thoracic radiculopathy, herpes zoster, rib fracture, costochondritis, and local contusion. History of trauma, ecchymosis, crepitus, and point tenderness over a rib suggests rib fracture. If the trauma was minor, a contusion or intercostal neuralgia may be the source of discomfort. Contusions typically improve quickly during a period of weeks and are responsive to simple analgesics, such as acetaminophen and nonsteroidal anti-inflammatory medications. In contrast, pain from intercostal neuralgia persists and can be refractory to acetaminophen, nonsteroidal anti-inflammatory drugs, and even low-dose narcotics.

Careful palpation along the thoracotomy scar or rib may reveal a neuroma with the presence of a Tinel sign. Larger neuromas can often be visualized on magnetic resonance imaging. Sensory examination often reveals a small (1 to 2 cm) band of dermatomal sensory loss.

Examination of the thoracic spine in patients with intercostal neuralgia reveals full active range of motion without tenderness. In contrast, thoracic radiculopathy may be accompanied by pain with range of motion and at times thoracic spinal tenderness. Still, pain from thoracic radiculopathy is similar in quality and distribution to intercostal neuralgia.

Intercostal neuralgia is distinct from postherpetic neuralgia (shingles), and no herpes zoster virus can be identified in cases of intercostal neuralgia. Furthermore, in most cases of shingles, the chest pain is followed within a matter of days

to weeks by a vesicular, linear eruption. The more debilitating pain of postherpetic neuralgia follows the skin lesions of shingles.

Functional Limitations

The pain of intercostal neuralgia is commonly mild to moderate but can be debilitating because it may interfere with one's ability to comfortably wear clothes. In one study, nearly 10% of post-thoracotomy patients observed for a mean of 19.5 months had moderate to severe pain that required daily analgesics, nerve blocks, relaxation therapy, acupuncture, or referral to a pain clinic [4]. The pain may also interfere with sleep. Trunk motion may stimulate the intercostal nerve, especially if a neuroma has formed. As a result, patients may begin restricting their activities.

Diagnostic Studies

Final diagnosis of intercostal neuralgia is often one of exclusion. Depending on which intercostal nerve is involved, chest pain from intercostal neuralgia may require an initial workup such as electrocardiography, cardiac enzyme analysis, cardiac computed tomography or magnetic resonance imaging, and other testing to exclude a cardiac source. Electromyographic recording of the paraspinal muscles is normal in intercostal neuralgia, whereas thoracic radiculopathy from thoracic disc herniation or foraminal stenosis may reveal active denervation potentials in the paraspinal muscles. Advanced imaging (thoracic magnetic resonance imaging, computed tomography, or computed tomographic myelography) also aids in demonstrating thoracic disc herniations or spinal stenosis as the source of the neural compression and confirms a diagnosis of thoracic radiculopathy. Larger intercostal neuromas may be visualized on magnetic resonance imaging of the ribs.

In the case of pain with a history of malignant disease, chest radiography, computed tomography, and bronchoscopy may be necessary to exclude recurrence of tumor. In patients whose history includes chest trauma, rib radiographs and at times bone scans help identify rib fractures.

Thoracic magnetic resonance imaging can exclude a disc herniation in an anatomically related area. Recall that it is not uncommon to identify asymptomatic disc herniations. In cases in which the disc protrusion does not cause clear compression but is abutting a thoracic nerve in the painful distribution, electrodiagnostic testing can exclude thoracic radiculopathy. Lesions of the intercostal nerve do not cause denervation in the thoracic paraspinal muscles.

When a postoperative neuroma is suspected, careful palpation often reveals a Tinel sign. Magnetic resonance imaging of the suspected area may reveal the neuroma. Small neuromas may be missed on magnetic resonance examination only to be identified later at the time of surgical resection.

Historical red flags including history of malignant disease, unexplained weight loss, malaise, and severe night pain raise the index of suspicion for rib metastases rather than intercostal neuralgia as the cause of the patient's chest pain. Appropriate oncologic workup, such as bone scans, laboratory investigation, and at times positron emission tomographic scans, should be performed.

Differential Diagnosis

Thoracic radiculopathy
 Malignant neoplasm (primary or metastatic)
 Rib fracture
 Vertebral compression fracture
 Chest wall contusion
 Postherpetic neuralgia
 Shingles
 Referred pain from cardiac, pulmonary, vascular, or gastrointestinal disease
 Angina
 Aortic dissection
 Myocardial infarction
 Esophageal disorders
 Cholecystitis
 Peptic ulcer disease
 Pancreatitis
 Biliary colic
 Pleurisy
 Pulmonary embolism
 Pneumothorax
 Costochondritis
 Tietze syndrome
 Nephrolithiasis
 Pyelonephritis
 Costovertebral or costochondral arthritis
 Spondylitis

Treatment

Initial

Thoracic radiculopathy, postherpetic neuralgia, and intercostal neuralgia are all forms of neuropathic pain, and they share many initial conservative treatment options. Principles of treatment of neuropathic pain in general, rather than of a specific disease state, are employed [13,14]. Typically, drugs have not been specifically tested on populations of patients with intercostal neuralgia. Instead, physicians are left to extrapolate the data from treatment of other sources of neuropathic pain and to apply those principles in choosing medication to be used for this population. Often, neuropathic pain responds poorly to acetaminophen, nonsteroidal anti-inflammatory drugs, and low-dose narcotics, in contrast to nociceptive pain [15,16]. However, if the pain is mild to moderate, these agents are often tried first. Topical agents may be effective when there is significant allodynia or dysesthesia. The patient may need a family member to help apply the topical agent because it may be difficult to reach the involved area. Capsaicin creams are available over-the-counter, and a newer capsaicin patch (Qutenza) is available by prescription (the actual indication is for postherpetic neuralgia). The cream requires frequent application three or four times a day and may initially cause an exacerbation of pain as substance P is depleted. Topical lidocaine applied as a gel, eutectic mixture of local anesthetics (EMLA), or patch (Lidoderm) is another alternative [17].

Tricyclic antidepressants (e.g., amitriptyline, nortriptyline, desipramine) have been used for neuropathic pain for decades [18]. The dosage for analgesia is typically lower than that required to treat depression. Onset of action may be in days to weeks. The mechanism of action in

neuropathic pain is believed to be modulation of descending inhibitory pathways by selective inhibition of norepinephrine or serotonin reuptake. Tricyclic antidepressants have anticholinergic effects and may cause confusion, increase the risk of falls and injury, and result in urinary retention. For these reasons, it is recommended that amitriptyline be avoided in persons older than 65 years. Despite this, amitriptyline (Elavil) is still a widely prescribed tricyclic antidepressant for neuropathic pain. It is usually started at 10 mg at bedtime and titrated upward as tolerated at 2- to 3-day intervals. Serotonin and norepinephrine reuptake inhibitors (SNRIs) such as duloxetine (Cymbalta), milnacipran (Savella), and venlafaxine (Effexor) are commonly used for neuropathic pain conditions, although only duloxetine is approved for a neuropathic diagnosis (painful diabetic neuropathy). Nausea can be seen with SNRIs. Milnacipran has a preference for norepinephrine reuptake inhibition and may lead to an increase in blood pressure. The SNRIs may be a better choice than the tricyclic antidepressants for elderly or debilitated patients with neuropathic pain.

Anticonvulsants are another mainstay for treatment of neuropathic pain. Anticonvulsants may work in several ways, including suppression of paroxysmal discharges and overall neuronal hyperexcitability [19]. Older agents such as carbamazepine and phenytoin have a narrow therapeutic window and risks of serious adverse drug reactions. These agents require careful monitoring if they are used. Bone marrow suppression occurs in up to 1% of patients, and severe dermatologic reactions such as Stevens-Johnson syndrome and epidermal necrolysis have also been reported with carbamazepine. Newer anticonvulsants, such as gabapentin (Neurontin) and pregabalin (Lyrica), are often chosen for their more favorable side effect profiles, efficacy, and limited interaction with other drugs. Gabapentin and pregabalin commonly cause sedation and may cause edema; both are indicated for neuropathic pain of diabetic peripheral neuropathy. These agents do not require blood samples for drug levels to be monitored. Dosing typically begins low and at night. For example, many practitioners start with gabapentin 300 mg at bedtime and titrate to 600 to 800 mg two or three times daily. At times, even higher doses are prescribed. Dosages are reduced in patients with renal insufficiency. Pregabalin can also be started at a low 50-mg bedtime dose and titrated to 300 mg twice daily, although it is uncommon to exceed 150 mg twice daily. Gabapentin and other anticonvulsants should be tapered before discontinuance. Like gabapentin and pregabalin, topiramate has also been used off-label for intercostal neuralgia [20].

Narcotics are often required for intercostal neuralgia. Adequate analgesia is needed to promote continued activity levels and to prevent deconditioning from disuse. Initial treatment should be with short-acting agents such as hydrocodone 5 mg with acetaminophen 325 mg every 4 hours as needed. Treatment of intercostal neuralgia can be protracted, and patients are often switched to long-acting agents for maintenance. If the pain is progressive, one should reevaluate the diagnosis and reconsider the possibility of occult tumor.

In refractory cases of neuropathic pain, clonidine, an adrenergic agonist, and ketamine, an *N*-methyl-D-aspartate

(NMDA) receptor antagonist, may be prescribed by pain specialists [10].

Rehabilitation

Physical and occupational therapy can be instrumental in combating disuse deconditioning. Also, desensitization techniques may be employed. Psychological consultation in patients who exhibit signs of anxiety, depression, or panic disorder may be beneficial to address the negative impact of these psychological stressors on the pain or the patient's behavior in response to the pain. Relaxation therapy and acupuncture have also been employed with anecdotal success [4].

If pain is severe, intercostal neuralgia may lead to avoidance of activity and deconditioning. It is important to keep patients physically active early in the rehabilitation process. The muscles of persons on strict bed rest lose 1.0% to 1.5% of their strength per day during a 2-week period. The loss is greatest during the first week of inactivity. Thus, if the patient is physically limited by pain, early prescription of a structured therapy program focusing on pain modulation helps prevent deconditioning. Desensitization techniques, heat, cold, and transcutaneous electrical nerve stimulation are all ways by which the therapist may assist in pain control while encouraging activity.

Psychological consultation in patients who exhibit signs of fear-avoidance, anxiety, and depression related to the pain may be beneficial later in the rehabilitation process. Biofeedback and relaxation therapy techniques are sometimes used. Biofeedback uses instrumentation to provide feedback on a variety of physiologic responses, such as muscle tension. It is typically used to facilitate relaxation and to enhance self-regulation. Two common relaxation therapies are autogenic training and progressive muscle relaxation. Relaxation training and biofeedback are thought to be equally effective in pain modulation.

Procedures

Local infiltration of a neuroma with corticosteroids and local anesthetics, intercostal nerve blocks, indwelling epidural catheters, and spinal nerve injections have all been used to control the pain associated with intercostal neuralgia when adequate relief is not achieved with oral and topical medications [2].

If a focal neuroma is identified, infiltration with several milliliters of local anesthetic with 40 mg of a long-acting corticosteroid, such as methylprednisolone (Depo-Medrol) or triamcinolone (Kenalog), often results in significant analgesia. In addition to its potent anti-inflammatory effect, the corticosteroid may also reduce neural discharges. Care must be taken during the injection to avoid pneumothorax.

Intercostal nerve blocks should be performed with appropriate monitoring. There are several techniques well described in interventional pain management books [21]. One common technique is to position the patient prone and to identify the angle of the rib just lateral to the sacrospinalis muscles (Fig. 103.3). The skin is moved up over the rib, and the needle is introduced down onto the posterior periosteum of the rib and then walked inferior. The advantage of moving the skin cephalad over the rib before needle insertion is that it allows the needle to be easily

FIGURE 103.3 Intercostal nerve injection technique. The needle is advanced over the rib. Initial contact indicates posterior depth of the nerve. The skin and needle are then moved inferiorly off the rib, with care taken to avoid advancement of the needle too far, causing a pneumothorax. (From Chung J. Thoracic pain. In Sinatra RS, Hord A, Ginsberg C, Preble L, eds. *Acute Pain*. St. Louis, Mosby, 1992.)

moved inferior after the needle contacts bone. At the angle of the rib, the rib is typically 8 mm thick. Great care must be taken not to overpenetrate and cause a pneumothorax; 3 to 5 mL of local anesthetic is instilled along with a long-acting corticosteroid, such as triamcinolone, methylprednisolone, betamethasone, or dexamethasone. The needle is then withdrawn slightly and moved back over the rib before safe removal. Another approach is midaxillary and may be preferred in postoperative and acutely ill patients who cannot be easily positioned prone.

If symptoms are well controlled with intercostal nerve blocks but recur, neurolytic injection of phenol or alcohol has been used to denervate the peripheral nerve [21]. Indwelling epidural catheters have been used to provide regional anesthesia with minimal drug use. A report of pregnant patients who developed intercostal neuralgias found this technique safe and effective [7].

Cryotherapy involves another way of interrupting the peripheral nerve's ability to transmit pain by freezing it. Cryotherapy has been used on neuromas and the involved intercostal nerve [22].

Spinal cord stimulators have been implanted for intercostal neuralgia but with less success than in neuropathic pain due to diabetic peripheral neuropathy and causalgia [23]. Chronic post-thoracotomy pain and intercostal neuralgia can be difficult to control. In one study, up to 40% of post-thoracotomy patients required pain procedures including trigger point injections, intercostal nerve blocks, epidural steroid injections, and stellate ganglion blocks [2].

Surgery

Surgical resection of a neuroma can be effective but should be reserved for cases that have failed more conservative care

and have demonstrated a temporary response to intercostal blocks. Dorsal root entry zone ablation involves surgical destruction of nociceptive secondary neurons in the spinal cord when pain is not adequately controlled with medical therapy [24,25]. The technique involves laminectomy with intradural exposure of the spinal cord. With an operating microscope, a radiofrequency probe is used to heat the dorsal horn of the affected side with a series of lesions.

Potential Disease Complications

Untreated upper intercostal neuralgia can potentially lead to a frozen shoulder as patients limit their use of the arm in response to the pain. Intercostal neuralgia can also cause a chronic pain syndrome with its comorbidities. Psychosocial dysfunction associated with chronic neuropathic pain includes impaired sleep, decreased appetite, and diminished libido.

Potential Treatment Complications

All medications carry risks. Many of the medications used for neuropathic pain (anticonvulsants, tricyclic antidepressants, narcotics) cause sedation. Injections in the area carry the risk of pneumothorax, bleeding, and infection. Surgical techniques may result in further nerve damage and pain, infection, bleeding, and pneumothorax.

ICD-9 Code

729.1 Myofascial pain syndrome

ICD-10 Code

M79.1 Myofascial pain syndrome

Definition

Myofascial pain syndrome (MPS) is a painful disorder characterized by the presence of myofascial trigger points (MTrPs), distinct sensitive spots in a palpable taut band of skeletal muscle fibers [1] that produce local and referred pain. Thus, MPS is characterized by both a motor abnormality (a taut or hard band within the muscle) and a sensory abnormality (tenderness and referred pain) [2] (Fig. 104.1). In addition to pain, the disorder is accompanied by referred autonomic phenomena as well as by anxiety and depression. The pathophysiologic mechanism of MPS is not clearly understood in part because of the scarcity of reliable valid studies. Moreover, concomitant disorders and frequent behavioral and psychosocial contributing factors in patients with MPS contribute to the complexity of human studies. Symptoms of MPS are generally associated with physical activities that are thought to contribute to “muscle overload,” either acutely by sudden overload or gradually with prolonged repetitive activity [3]. MPS is reported to be prevalent in regional musculoskeletal pain syndromes; however, the syndrome can be classified as regional or generalized. Some authors broaden the definition of myofascial pain to

include a regional pain syndrome of any soft tissue origin. Thus, MPS may be considered either a primary disorder causing local or regional pain syndromes or a secondary disorder that occurs as a consequence of some other condition, such as a radiculopathy.

The MTrP is generally considered the hallmark of MPS; therefore, much attention has been given to characteristic features of MTrPs in skeletal muscle [4,5]. One such feature of the MTrP is the so-called twitch response. This local response is considered a characteristic finding of the MTrP. Mechanical stimulation (“snapping” palpation, pressure, or needle insertion) can elicit a local twitch response that frequently is accompanied by referred pain [6]. The twitch response is accompanied by a burst of electrical activity (“end-plate noise”) within the muscle band that contains the activated trigger point, whereas no activity is seen at other muscle bands. End-plate noise is significantly more prevalent in MTrPs than in sites that lie outside of the MTrP but still within the end-plate zone [7]. This observation has been attributed to a spinal reflex [4,6], as the response is abolished by motor nerve ablation or infusion of local anesthetic. Moreover, spinal cord transection above the neurologic level of the MTrP fails to permanently alter the characteristic response.

A number of hypotheses [8,9] have been put forward to explain the findings observed in MTrPs. One theory proposes that MTrPs are found only at the muscle spindle in an attempt to explain beneficial effects of α -adrenergic antagonists. However, this idea does not fully explain the electromyographic findings recorded at the MTrP. Further, there appears to be little evidence that painful muscle areas, such as MTrPs, are associated with any structural changes, such as an alteration in the appearance of the muscle spindle. Another theory is related to excessive release of acetylcholine in abnormal end plates [4], as the electromyographic activity recorded at trigger points resembles findings described at the end-plate region [7]. This idea has led some clinicians to study effects of botulinum toxin injection into MTrPs in an attempt to reduce release of excessive acetylcholine. To date, results of small cohort studies [10] examining effects of botulinum toxin on MTrPs have yielded inconsistent findings.

Central neurologic processes are increasingly viewed as essential factors in chronic pain syndromes. The medial

Digital pressure at 45-degree angle introduces ischemic, inhibitory pressure.

Various models exist:

- ✓ Temporarily cuts off circulation, “flushing” tissues when released
- ✓ Inhibition of neural activity
- ✓ Local mechanoreceptors stimulated, producing gating of pain messages
- ✓ Release of local endorphins and brain enkephalins
- ✓ Mechanical stretching of tissues
- ✓ Alters gel-like tissues to softer “sol” state
- ✓ Taut bands associated with trigger point’s release
- ✓ Enhanced energy flow according to TCM

FIGURE 104.1 Schematic representation of myofascial trigger point. TCM, traditional Chinese medicine. (From Chaitow L. *Modern Neuromuscular Techniques*, 3rd ed. New York, Churchill Livingstone, 2011.)

thalamus is the principal relay of nociceptive input to the anterior cingulate cortex, and persistent stimulation of this pathway by pain in peripheral tissues has been demonstrated to change neurons in the cingulate cortex [11]. Thus, persistent pain is associated with long-term changes in the morphology, neurochemistry, and gene expression of the anterior cingulate cortex, which has the most direct connection with autonomic arousal, thereby contributing to the maintenance and exacerbation of pain [12].

Such central sensitization is characterized by an enhanced pain response to normally painful stimuli (hyperalgesia), a decrease in pain threshold to normally nonpainful stimuli (allodynia), and an increase in spontaneous activity (spontaneous pain). This process is clinically seen in MPS as the pain–muscle tension (in response to autonomic arousal and affective distress)—increased pain–increased tension and distress cycle.

Fibromyalgia (see Chapter 101), a chronic musculoskeletal pain condition that predominantly affects women, is characterized by diffuse muscle pain, fatigue, sleep disturbance, depression, and skin sensitivity [13]. Fibromyalgia may fit the classification of MPS as the diagnosis includes the presence of 11 of 18 tender points [14]. Furthermore, treatment of MPS and fibromyalgia is similar as evidence supports the role of exercise, cognitive-behavioral therapy, education, and social support in the management of both fibromyalgia and chronic MPS. However, there is controversy as to whether fibromyalgia and MPS represent specific pathologic processes or are descriptive terms of clinical conditions. Objective evidence of muscle abnormalities in fibromyalgia has been demonstrated by histologic studies showing disorganization of Z bands and abnormalities in the number and shape of muscle mitochondria. Biochemical studies and magnetic resonance spectroscopy have also shown inconstant abnormalities of adenosine triphosphate and phosphocreatine levels. It is unclear whether these abnormalities are a result of physical deconditioning or if abnormalities are due to problems in energy metabolism. There are no clear biochemical markers that distinguish

patients with fibromyalgia. Thus, whereas the pathogenesis is still unknown, there has been evidence of increased corticotropin-releasing hormone and substance P in the cerebrospinal fluid of fibromyalgia patients as well as increased substance P and interleukins 6 and 8 in their serum [14]. One hypothesis supports the idea that fibromyalgia is an immunoendocrine disorder in which increased release of corticotropin-releasing hormone and substance P from neurons triggers local mast cells to release proinflammatory and neurosensitizing molecules. This hypothesis fits well with recent discoveries of neuropeptides found in the muscles of patients with active MTrPs [15].

Symptoms

The patient with MPS generally complains about dull or achy pain, sometimes poorly localized, particularly occurring during repetitive activities or during activities requiring sustained postures. Symptoms are exacerbated with digital pressure over tender areas of muscle with reproduction of the patient’s usual pain. Symptoms are relieved with rest or cessation of repetitive activities. In contrast, the patient with fibromyalgia typically presents with sleep disturbances, depressed mood, and fatigue.

Physical Examination

The most important part of the physical examination is generally considered to be finding and localizing MTrPs to provide an accurate diagnosis of MPS. *Travell & Simons’ Myofascial Pain and Dysfunction: The Trigger Point Manual* [16] is considered the criterion standard reference on locating and treating MTrPs. Active MTrPs, attributed to cause pain, exhibit marked localized tenderness and may refer pain to distant sites, disturb motor function, or produce autonomic changes. Specific clinical training is required to become adept at identifying MTrPs as evidence suggests that “non-trained” clinicians do not reliably detect the taut band and local twitch response [17].

FIGURE 104.2 Flat palpation technique useful in examining muscles that are accessible only from one side. **A**, Index finger pushes skin to one side. **B**, Fingertip sweeps across the muscle to feel the taut band rolling beneath. **C**, Skin is pushed to the other side, completing the movement. When it is done vigorously, this technique is called snapping palpation. (From Simons DG, Travell JG, Simons LS. *Travell & Simons' Myofascial Pain and Dysfunction: The Trigger Point Manual*, 2nd ed. Baltimore, Williams & Wilkins, 1999.)

To clinically identify MTrPs, the clinician palpates a localized tender spot in a nodular portion of a taut, rope-like band of muscle fibers. Manual pressure over a trigger point should elicit pain at that area and may also elicit pain at a distant site (referred pain) from the point under the fingertip (Fig. 104.2). MTrPs, when palpated, should also elicit pain that mirrors the patient's experience. Applied pressure often reproduces the pain. Insertion of a needle, abrupt palpation, or even a brisk tap with the fingertip directly over the trigger point may induce a brief muscle contraction detectable by the examiner. This rapid contraction of muscle fibers of the ropy taut band is termed a local twitch response [3]. In muscles that move a relatively small mass or are large and superficial (such as the finger extensors or the gluteus maximus), the response is

easily seen and may cause the limb to visibly move when the examiner introduces a needle into the trigger point. Localized abnormal response from the autonomic nervous system may cause piloerection, localized sweating, or even regional temperature changes in the skin attributed to altered blood flow [8,18,19].

Regional Examination of the Lower Extremity for Piriformis Syndrome

To evaluate individuals for piriformis syndrome [20], their usual buttock, hip, and lower limb pain may be reproduced during the following maneuvers: palpation over a point midway between the sacrum and greater trochanter of the femur, active hip abduction in the lateral recumbent position, and rectal palpation of the ipsilateral side of the involved limb [21,22]. Beatty described a maneuver [23,24] performed with the patient's lying with the painful side up, the painful leg flexed, and the knee resting on the table. Buttock pain is produced when the patient lifts and holds the knee several inches off the table. A positive finding in at least two of the preceding maneuvers is sufficient to confirm a diagnosis of piriformis syndrome, provided other potential causes have been eliminated from the differential diagnosis.

Diagnostic Studies

No definitive laboratory test or imaging method is diagnostic of MPS. Thus, diagnosis is made primarily by history and physical examination. Whereas no specific laboratory tests confirm (or refute) a diagnosis of MPS [25,26], some tests can be helpful in looking for predisposing conditions, such as hypothyroidism, hypoglycemia, and vitamin deficiencies. Specific tests that may be helpful include complete blood count, chemistry profile, erythrocyte sedimentation rate, and levels of vitamins C, B₁, B₆, B₁₂, and folic acid. If clinical features of thyroid disease are present, an assay for thyrotropin may be indicated [27].

Differential Diagnosis

- Fibromyalgia
- Trochanteric bursitis
- Neuropathic pain
- Postexercise muscle soreness
- Articular dysfunction
- Referred pain

Treatment

Initial

Therapeutic modalities such as biofeedback, ultrasound, lasers, and massage may be useful adjuncts in relieving initial pain to allow participation in an active exercise program [28]. Data suggest that addition of therapeutic physical modalities [1,3,25,29], such as heat, and various forms of muscle and nerve stimulation are beneficial in the initial treatment of MPS.

Nonsteroidal anti-inflammatory drugs (NSAIDs) may be a useful adjunct to active exercise-based treatment of MPS, but NSAIDs are generally considered beneficial when they are used in conjunction with an active treatment program. However, no randomized placebo-controlled clinical trials exist to support efficacy of NSAIDs in this condition. Interestingly, the NSAID diclofenac, when it is injected into the MTrP, was shown to be superior to lidocaine in one small clinical trial [30]. Low-dose amitriptyline is widely used in patients with fibromyalgia and is thought to help improve the patient's sleep cycle [31]. Muscle relaxants may also provide benefit to patients with MPS. For example, cyclobenzaprine hydrochloride, a commonly prescribed muscle relaxant, is indicated as an adjunct to rest and physical therapy for the relief of muscle spasm associated with acute, painful musculoskeletal conditions. In contrast to low-dose (5 mg three times daily) cyclobenzaprine, a higher dose (10 mg three times daily) is associated with more somnolence and dry mouth. Importantly, there does not appear to be a relationship between somnolence and pain relief. A large, multicenter, community-based trial of patients with acute pain and muscle spasm evaluated low-dose cyclobenzaprine (5 mg three times daily) alone compared with combination therapy with two doses of ibuprofen. It is possible that low-dose cyclobenzaprine or high-dose ibuprofen alone may be sufficient to relieve acute musculoskeletal pain and that no additional benefit is incurred by adding another medication. Future trials comparing various doses of muscle relaxants and NSAIDs alone or in combination will be required to address these questions in the treatment of patients with MPS.

Rehabilitation

Physical therapy techniques that focus on correction of muscle shortening by targeted stretching, strengthening of affected muscles, and correction of aggravating postural and biomechanical factors are generally considered to be the most effective treatment of MPS [32–34]. This idea is supported by a line of evidence examining the relationship between muscle overload and MTrPs [33,35], suggesting a direct relationship between exercise and MPS.

The goal for the treatment of MPS is to engage patients in active therapy to prevent the development of chronic pain syndrome or to rehabilitate patients from its disabling interacting symptoms if it has developed. Chronic MPS is not a diagnosis but a descriptive term for individuals who not only report persistent pain but also evidence poor coping, self-limitations in functional activities, significant life disruption, and dysfunctional pain behavior [36]. Other common symptoms of chronic pain syndrome related to an accompanying disuse syndrome include the multiple physical systems effects of deconditioning as well as insomnia, fatigue, anxiety, and depression [37]. A central feature of chronic MPS is a disability conviction and resulting avoidance of activity based on the fear that engaging in functional activity will increase pain (fear-avoidance) [37]. The critical importance of addressing such a belief is underlined by prior studies indicating that patients' beliefs about their pain are the best predictors of task performance [38], medical utilization [39], and long-term rehabilitation [40].

Preventing the development of such a disability conviction begins by assisting patients to shift from a biomedical perspective, in which there is an ongoing search for the cause of an illness to be "cured" or "fixed," to a biopsychosocial rehabilitation perspective [37,40]. This perspective views MPS as a multifactorial condition that need not be disabling if it is actively managed by the patient. Cognitive-behavioral therapy is the psychological approach that focuses on changing dysfunctional beliefs or "schemas" by which individuals process, store, and act on information [41]. For individuals with chronic pain to successfully participate in a functionally oriented rehabilitation approach, they need to understand or to believe the following:

1. The nature of the pain has been thoroughly evaluated, and there is no cure (i.e., surgery or another procedure) for the pain.
2. The rehabilitation approach involving physical activity and conditioning will increase functional capabilities and eventually reduce suffering.
3. The hurt engendered through physical conditioning will not cause harm.
4. Reinjury or worsening of the painful condition is unlikely, and it is in the individual's best interest to become more functional.

The first point most often can be addressed by the physician in the office, but the critical shift in belief that hurt will not cause harm generally requires the patient to have repeated experiences that contradict the prior life experience that if something hurts, you should stop doing it. For a patient with MPS to exercise consistently and sufficiently to contradict the common sense to avoid pain, an interdisciplinary team approach is often required. In such an approach, the physical therapist educates and guides the patient through a progressive physical reconditioning regimen. The physician periodically reevaluates the patient, reassuring and encouraging the patient that there is no problematic change in condition while adjusting medications to facilitate involvement in the program. Concurrently the psychologist provides training in stress management, pacing, and pain coping strategies. This is often best done in a group setting that normalizes the reactions and experience of the patient and where the social support and encouragement of the patient's peers is of significant benefit. Ultimately, though, it is the patient's repeated mild increases in pain without harm, as functioning improves, that change beliefs about pain and fear-avoidance of activity. It is largely for this reason that multidisciplinary pain programs that include a cognitive-behavioral approach have been found to be most effective for individuals with chronic pain on a range of key outcomes [42]. A cognitive-behavioral, functional restoration approach is particularly effective for chronic MPS because unlike in many other chronic pain conditions, one can be fairly certain that the hurt experienced through increased activity will not only not cause harm but will lead to long-term benefit.

Hypnosis

In addition to the cognitive changes noted, patients should be educated on the interacting effects of pain leading to increased sympathetic arousal ("stress response") that leads to increased muscle tension and increased pain. They therefore can reduce pain by reducing their reactivity to pain as

well as other stressors in their life. Techniques for doing so include relaxation training, progressive muscle relaxation, mindfulness meditation, and hypnosis. Hypnosis is increasingly being integrated into multidisciplinary treatment approaches because it enables one to train patients to develop a relaxation response while also interspersing suggestions to encourage the changes in thinking noted before [43–51]. In other words, hypnosis is a tool that can be used not only to assist patients in reducing their attention to the sensation of pain but, more important, to reduce their affective distress and autonomic reactivity.

Mindfulness Meditation

Another approach to reducing affective distress and autonomic reactivity in response to pain that has received increasing attention is mindfulness meditation. Mindfulness has been defined as “paying attention in a particular way: on purpose, in the present moment, and nonjudgmentally.” [52] Zeidan and colleagues [53] expanded on this description to operationally define mindfulness as involving “(a) regulated, sustained attention to the moment-to-moment quality and character of sensory, emotional and cognitive events, (b) the recognition of such events as momentary, fleeting and changeable (past and future representations of those events being considered cognitive abstractions), and (c) a consequent lack of emotional or cognitive appraisal and/or reactions to these events.” Pragmatically, this tends to involve training in focused attention (Samatha meditation) and open awareness (Vipassana meditation). One is taught that such thoughts are momentary and fleeting and that one need not react to them. Whereas mindfulness-based stress reduction has been viewed as the “gold standard,” there have been variations including mindfulness-based cognitive therapy [54]. For example, brief mindfulness training can have a significant impact on experimentally induced pain and cognition [53]. Although the specific mechanisms remain unclear, accruing evidence indicates that through processes of neuroplasticity, significant changes can occur in brain structures associated with the processing of pain, especially the prefrontal and anterior cingulate cortices [55]. In this way, one can therapeutically use the neuroplasticity of the brain to enhance pain control, in a manner that is the reverse of central sensitization described before.

Procedures

In combination with other therapies, interventional techniques can be an effective adjunct in the multidisciplinary management of patients with MPS [56]. In the treatment of MPS, other than trigger point injections, interventional procedures (e.g., epidural steroid injections, sacroiliac joint injections, and medial branch blocks) are usually not employed. However, at times, myofascial pain is associated with or caused by other underlying conditions. For instance, lumbar myofascial pain may also have some component of lumbar facet arthropathy. Lumbar medial branch blocks and radiofrequency denervation, alone or in combination with the other therapies (e.g., muscle relaxants), may work together to relieve myofascial pain. Similarly, epidural steroid injection may provide lumbar pain relief in a patient with spondylosis. It has been suggested that epidural steroid injections may be used to treat cervical MPS if conservative

treatments fail [57]. Therefore, underlying disease may respond to more aggressive interventional methods and in turn synergistically provide pain relief to the patient with MPS.

MTrP injections should be individualized for both the patient and the clinician. Alcohol, if it is used to clean the skin, should be allowed to dry completely to prevent additional pain. Use of operating rooms or special procedure (sterile) rooms equipped with monitoring devices for the purpose of intramuscular injections with small-caliber needles is not necessary. Most patients can be treated safely in an office setting by experienced clinicians. The diagnostic skill required to find active MTrPs depends on considerable innate palpation ability, authoritative training, and extensive clinical experience [3]. Application of trigger point injection begins by determining the equipment needs according to the needs of the patient, the clinician's training, and the anatomic target for injection. Typically, a 1.0-mL tuberculin-type syringe with $\frac{5}{8}$ -inch 25-gauge needle is adequate for superficial muscles. For small muscles (e.g., facial muscles), a 1-inch 30-gauge needle is sufficient. For larger muscles, a 1-inch or 1½-inch 25-gauge needle is adequate. After the patient is placed in a position in which the desired muscle can be relaxed, the MTrP is located. In the prone position, the MTrP is ascertained by gentle pressure from the end of a fingertip or a ballpoint pen applied at regular 1-cm intervals. The patient is observed closely during the palpation because pressure on the markedly tender MTrP usually causes the patient to jump, to wince, or to cry out. Each muscle has a characteristic elicited referred pain pattern that, for active MTrPs, is familiar to the patient. Thus, the patient will respond that this pressure reproduces the usual pain and, when questioned, will describe painful sensations at a site slightly distant to the point under the examiner's finger. Once the MTrP has been located, the skin is marked, and the site is injected with saline, anesthetic agent, or corticosteroid solution. Once the MTrP has been located, the skin is marked and prepared. The site is injected with no more than 1 mL injectate per site after negative aspiration for blood. When the needle is advanced to the MTrP, it may elicit a local twitch response, although a local twitch response is not observed all the time despite significant improvement of myofascial pain with trigger point injection. Other findings that may help determine the needle entrance to the MTrP are the patient's confirmation of reproduction of the usual pain pattern and the clinician's sensation of increased resistance as the needle is advanced from normal muscle tissue to the taut band.

Surgery

Surgery is not indicated in the treatment of patients with MPS.

Potential Disease Complications

Patients with MPS may go on to develop chronic pain syndrome. Treatment of individuals with chronic MPS is described earlier. Perhaps the biggest complication of untreated and progressive MPS is development of a syndrome of physical inactivity that may lead to cardiovascular disease. Evidence of a dose-response relation between physical activity and cardiovascular disease endpoints has been

proposed [58], although the majority of the literature in this area has relied on prospective observational studies, and few randomized trials of physical activity and cardiovascular disease as a clinical outcome have been reported. This notwithstanding, evidence indicates that cardiovascular disease incidence and mortality are causally related to physical activity in an inverse, dose-response fashion. Thus, left untreated, patients with MPS who go on to develop chronic pain and lack physical activity are at high risk for cardiovascular disease and early death.

Potential Treatment Complications

The greatest risk of treatment of the patient with MPS is related to MTrP injections in the thoracic area. Because of the anatomic location of the apex of the lung to the proximity of the upper trapezius muscle or the scalene muscles, the clinician must be aware of the potential for pneumothorax as a result of MTrP injection in this area. The use of long (>1 inch) small-gauge needles should be avoided because long, thin needles can easily bend once they are inserted into the muscle, and the tip can inadvertently puncture the pleura. Rather, short (<1 inch) needles should be used for MTrP injections anywhere near the apex of the lung. In addition, the needle should be directed away from structures at risk of inadvertent puncture. To provide additional proprioceptive feedback during injection, grasping the muscle between the thumb and forefinger will allow the clinician to palpate the thickness of the tissue to be injected. Thin patients or those with reduced lung capacity from underlying diseases are particularly at risk, and thus the clinician should use extra precautions when performing MTrP injections in these patients.

M54.81 Occipital neuralgia

Definition

The International Headache Society categorizes occipital neuralgia as a cranial neuralgia and defines it with three diagnostic features: paroxysmal stabbing pain in the distribution of the occipital nerves with tenderness over the affected nerves temporarily relieved by local anesthetic block [1]. Occipital neuralgia can occur in the distribution of the greater and lesser occipital nerves (Fig. 105.1). However, the greater occipital nerve is more commonly involved (90%); in addition, unilateral symptoms are more common (85%) [2]. The condition appears to be more common in women [3].

The pain is described as lancinating, sharp, throbbing, electric shock-like, and often associated with posterior scalp dysesthesia or hyperalgesia [4–6]. Two broad categories of patients with occipital neuralgia are those with structural pathologic changes and those without an apparent

cause [7]. Proposed causes include myofascial tightening, trauma of C2 nerve root (whiplash injury), prior skull or suboccipital surgery, other type of nerve entrapment, hypertrophied atlantoepistropheic (C1-C2) ligament, sustained neck muscle contractions, and spondylosis of the cervical facet joints [2,4,6,8–10]. Most patients with occipital neuropathy do not have discernible lesions [11].

Anatomy

The greater occipital nerve innervates the posterior skull from the suboccipital area to the vertex. It is formed from the medial (sensory) branch of the posterior division of the second cervical nerve [8]. It emerges between the atlas and lamina of the axis below the oblique inferior muscle and then ascends obliquely on this muscle between it and the semispinalis muscle [8]. The course of the greater occipital nerve does not appear to differ in men and women [12]. The lesser occipital nerve forms from the medial (sensory) branch of the posterior division of the third cervical nerve, ascends like the greater occipital nerve, and pierces the splenius capitis and trapezius muscles just medial to the greater occipital nerve [8]. It ascends along the scalp to reach the vertex, where it provides sensory fibers to the area of the scalp lateral to the greater occipital nerve.

The roots of the first two cervical nerves are not protected posteriorly by pedicles and facets because of the unique articulation of the atlas and axis relative to the rest of the spinal column. Thus, the first two cervical nerves are relatively vulnerable to injury. The joint between the atlas and occiput, between which the first cervical nerve emerges, is relatively immobile compared with the lower C1-C2 articulation. Thus the C2 nerve root emerges unprotected through a highly mobile joint, and this may explain the predominance of greater occipital nerve involvement in occipital neuralgia [13].

Symptoms

Although occipital neuralgia is defined by the International Headache Society as a paroxysmal headache, some patients complain of continuous pain [2]. In continuous occipital neuralgia, the headaches may be further classified as acute or chronic.

Paroxysmal occipital neuralgia describes pain occurring only in the distribution of the occipital nerve. The attacks are generally unilateral, and the pain is sudden and severe.

FIGURE 105.1 Occipital nerve anatomy. The greater occipital nerve pierces the fascia just below the superior nuchal ridge along with the artery. It supplies the medial portion of the posterior scalp. The lesser occipital nerve passes superiorly along the posterior border of the sternocleidomastoid muscle, dividing into the cutaneous branches that innervate the lateral portion of the posterior scalp and the cranial surface of the pinna. (From Waldman SD. *Greater and lesser occipital nerve block*. In Waldman SD, ed. *Atlas of Interventional Pain Management*, 2nd ed. Philadelphia, WB Saunders, 2004.)

The patient may describe the pain as sharp, twisting, a dagger thrust, or an electric shock. The pain rarely demonstrates a burning characteristic. Although single flashes of pain may occur, multiple attacks are more frequent. The attacks may occur spontaneously or be provoked by specific maneuvers applied to the back of the scalp or neck regions, such as brushing the hair or moving the neck [11].

Acute continuous occipital neuralgia often has an underlying cause. Exposure to cold is a common trigger [14]. The attacks last for many hours and are typically devoid of radiating symptoms (e.g., trigger zones to the face). The entire episode of neuralgia can continue up to 2 weeks before remission.

In chronic continuous occipital neuralgia, the patient may experience painful attacks that last for days to weeks. These attacks are generally accompanied by localized spasm of the cervical or occipital muscles. The reported pain originates in the suboccipital region up to the vertex and radiates to the frontotemporal region. Radiation to the orbital region is also common. Sensory triggers to the face or skull can initiate a painful episode. Similarly, pain may increase with pressure of the head on a pillow. Prolonged abnormal fixed postures that occur in reading or sleeping positions and hyperextension or rotation of the head to the involved side may provoke the pain. The pain may be bilateral, although the unilateral pattern is more common. Often, a previous history of cervical or occipital trauma or arthritic disease of the cervical spine is obtained. On occasion, patients may report other autonomic symptoms concurrently, such as nausea, vomiting, photophobia, diplopia, ocular and nasal congestion, tinnitus, and vertigo [11]. Severe ocular pain has also been described, as have symptoms in other distributions of the trigeminal nerve [9,10,12,13]. Convergence

of sensory input from the upper cervical nerve roots into the trigeminal nucleus may explain this phenomenon [13]. Occipital neuralgia may occur in combination with other types of headaches. For example, one study found concurrent migraine in 20 of 35 consecutive patients presenting with occipital neuralgia [14].

Physical Examination

On examination, pain is generally reproduced by palpation of the greater and lesser occipital nerves. Allodynia or hyperalgesia may be present in the nerve distribution. Myofascial pain may be present in the neck or shoulders. Pain may limit cervical range of motion. Neurologic examination findings of the head, neck, and upper extremities are generally normal.

Entrapment of the nerve near the cervical spine may result in increased symptoms during flexion, extension, or rotation of the head and neck. Compression of the skull on the neck (Spurling maneuver), especially with extension and rotation of the neck to the affected side, may reproduce or increase the patient's pain if cervical degenerative disease is the cause of the neuralgia [11]. Pressure over both the occipital nerves along their course in the neck and occiput or pressure on the C2-C3 facet joints should cause an exacerbation of pain in such patients, at least when the headache is present. Even if the actual pathologic process is in the cervical spine, tenderness over the occipital nerve at the superior nuchal line is usually present.

Functional Limitations

In general, there are no neurologic deficits from occipital neuralgia. However, the pain from this entity may result in significant limitations in activities of daily living. During exacerbations, patients may have significant functional limitations, including insomnia, loss of work time, and inability to perform physical activity or to drive a vehicle. Tasks that involve the cervical spine or upper extremities, such as talking on the telephone, working at the computer, reading a book, cooking, gardening, and driving, may be painful and limited.

Diagnostic Studies

The diagnosis of occipital neuralgia is generally made clinically on the basis of history and physical examination. Imaging may help confirm the diagnosis when there is an anatomic cause. Diagnostic local anesthetic nerve blocks may be required for a definitive diagnosis to be obtained; these blocks are done with or without the addition of corticosteroid [5,8,11]. The relief of pain after a diagnostic local anesthetic block of the greater and lesser occipital nerves is generally confirmatory of the diagnosis of occipital neuralgia.

In addition, magnetic resonance imaging or computed tomography of the cervical spine should be performed to rule out an anatomic cause, such as tumor, vascular malformation, infection, or spondylotic arthritis, that may be compressing the medial (sensory) branches of C2-C3 [15]. Radiographs may be obtained to rule out gross abnormalities as an initial screening test but will not generally provide the

level of detail needed for diagnostic purposes. Single-photon emission computed tomography and positron emission tomography are being increasingly used for diagnosis and treatment of certain headache syndromes and may be useful in occipital neuralgia if there is functional pathologic change involved or in trying to distinguish between occipital neuralgia and cluster or migraine headache [13]. Radiologic degenerative changes of the cervical spine do not necessarily correlate with the patient's symptoms and examination findings, but C2-C3 arthritic changes in the absence of other gross or radiographic abnormalities may explain the etiology. Other rare causes of occipital neuralgia reported in the literature include upper respiratory tract infection [16], herpes zoster infection or postherpetic neuralgia [17], myelitis [18], hypermobile C1 vertebra [19], and giant cell arteritis [20,21]. In patients with unilateral headaches in the distribution of the greater occipital nerve, ultrasonography can show enlargement of the ipsilateral nerve compared with the uninjured contralateral nerve and thus lend further evidence to the diagnosis of occipital neuralgia [22].

Differential Diagnosis

- C2-C3 subluxation or arthropathy
- C2-C3 radiculopathy
- Migraine headache
- Cluster headache
- Tension-type headache
- Tumor (e.g., posterior fossa)
- Congenital or acquired abnormalities at the craniocervical junction (e.g., Arnold-Chiari malformation or basilar invagination)
- Rheumatoid arthritis
- Atlantoaxial subluxation
- Cervical myelopathy
- Pott disease—osteomyelitis
- Paget disease
- Vascular abnormalities
- Herpes zoster or postherpetic neuralgia
- Giant cell arteritis
- Trauma
- Whiplash injury

Treatment

Initial

Treatments that may help with pain from occipital neuralgia include heat or cold therapy, massage, avoidance of excessive cervical spine flexion-extension or rotation, acupuncture, and application of transcutaneous electrical nerve stimulation.

Pharmacologic therapy with nonsteroidal anti-inflammatory drugs or acetaminophen as well as other analgesics may be used. Tricyclic antidepressants, anticonvulsants, and muscle relaxants may also prove useful. Anticonvulsants such as carbamazepine, gabapentin, and pregabalin have been used for neuropathic pain with good results. Certain patients with comorbid psychological stressors may have pain complaints out of proportion to physical examination findings and should have their psychological symptoms treated with appropriate medications and psychological or cognitive-behavioral therapy.

Patients will often benefit from adaptive equipment at home and work, such as a telephone earset or bookstand. It is also important to determine whether patients are using bifocal glasses and whether adjusting the neck to use these glasses is contributing to the condition.

Rehabilitation

The incorporation of stretching and strengthening exercises for the paracervical and periscapular muscles may be appropriate for the patient with subacute or chronic occipital neuralgia, particularly if the condition is provoked by cervical spine or trunk movement. Postural training and relaxation exercises should be incorporated into the exercise regimen. Principles of ergonomics should be addressed if work site activity is limited by pain exacerbations (e.g., use of a telephone headset, document holder) [11]. An ergonomic workstation evaluation may be beneficial.

Manual therapy, including spinal manipulation and spinal mobilization, has been used to treat patients with cervicogenic headaches. A review of trials done with spinal manipulation for cervicogenic headache revealed two with positive results regarding headache intensity, headache duration, and medication intake [23]. Only one trial showed a decrease in headache frequency. There is clearly a need for more well designed randomized controlled trials to evaluate these therapies [24]. Any spinal manipulation should be done with caution because there are serious risks if it is improperly performed [25]. Anecdotal reports support a trial of cervical traction in some cases [11].

Procedures

Blockade of the greater or lesser occipital nerve with a local anesthetic is diagnostic and therapeutic (Fig. 105.2). Pain relief can vary from hours to months. In general, at least 50% of patients will experience more than 1 week of relief after one injection. Isolated pain relief for more than 17 months has been reported after a series of five blocks [7]. The addition of a cortisone preparation is controversial, but it may provide additional benefit [3]. Botulinum toxin A injection into the greater occipital nerve has also been described [3], but the evidence is limited. Its use is currently ranked as grade C, the weakest strength recommendation [26]. Classically, landmark techniques have been used in occipital nerve blockade. Ward [27] described one such blind technique wherein the greater occipital nerve is found medial to the occipital artery along the superior nuchal line. Nerve stimulator-guided blocks [28] and computed tomography-guided blocks [6] have also been described. An ultrasound-guided technique was recently demonstrated [29] and postulated as superior to traditional landmark techniques in light of known variation of the greater occipital nerve [30], but clinical studies have not confirmed this presumption.

Dorsal rhizotomy of C1, C2, C3, and C4 has been described; about 71% to 77% of patients report significant benefit [7,25–27]. Before dorsal rhizotomy, local anesthetic blockade of the suspected medial (sensory) branches should be performed for diagnostic purposes.

Pulsed radiofrequency to the culprit occipital nerve was shown to improve symptoms for 6 months or more [31].

FIGURE 105.2 Occipital nerve block. The patient is placed in a sitting position with the cervical spine flexed and the forehead on a padded bedside table. A total of 8 mL of local anesthetic is drawn up in a 12-mL sterile syringe. A total of 80 mg of depot steroid is added to the local anesthetic with the first block and 40 mg with subsequent blocks. The occipital artery is palpated at the level of the superior nuchal ridge. After preparation of the skin with antiseptic solution, a 22- or 25-gauge, 1½-inch needle is inserted just medial to the artery and advanced perpendicularly until the needle approaches the periosteum of the underlying occipital bone. A paresthesia may be encountered. The needle is then redirected superiorly, and after gentle aspiration, 5 mL of solution is injected in a fan-like distribution, with care being taken to avoid the foramen magnum. (From Waldman SD. *Greater and lesser occipital nerve block*. In Waldman SD, ed. *Atlas of Interventional Pain Management*, 2nd ed. Philadelphia, WB Saunders, 2004.)

A more recent report demonstrated benefit from pulsed radiofrequency in a significant portion of patients with treatment-refractory occipital neuralgia [32].

Surgery

One should consider surgical treatment after conservative therapy has failed, including but not limited to membrane stabilizers, tricyclic antidepressants, opioids, spinal manipulation, occipital nerve or cervical medial branch blocks, and partial posterior rhizotomy of C1-C3 [6]. Reversible interventions may be considered before destructive, irreversible

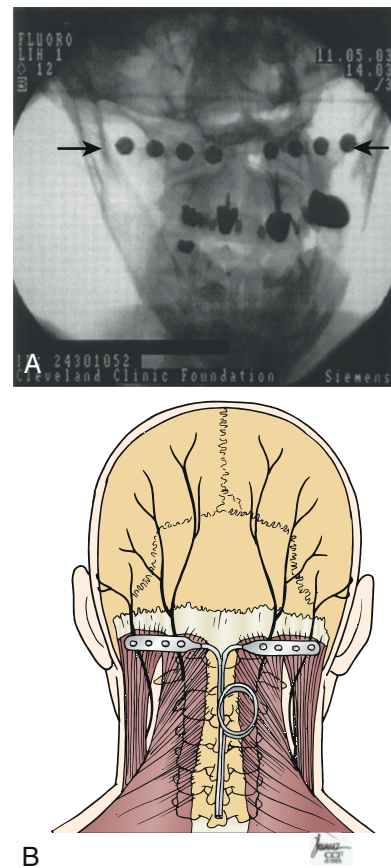

FIGURE 105-3 Occipital nerve stimulation. Radiograph (A) and schematic (B) of the midline subcutaneous approach in surgical lead positioning for electrical stimulation of the occipital nerve. A, Bilateral position of subcutaneous leads (arrows) after initial adjustment and just before intraoperative stimulation testing. Note that both leads are at the level of C1-C2 dens and aimed laterally. B, Schematic of the lead positioning in the subcutaneous occipital area. Note that the lead cable extensions form the loop just below the implant's position and through the same midline incision. (From Kapural L, Mekhail N, Hayek SM, et al. *Occipital nerve electrical stimulation via the midline approach and subcutaneous surgical leads for treatment of severe occipital neuralgia: a pilot study*. *Anesth Analg* 2005;101:171-174.)

surgical procedures [33]. In 1999, Weiner and Reed described successful treatment of occipital neuralgia with neurostimulation, whereby subcutaneous implantation of electrical leads in the suboccipital region modulates afferent pain nociceptive fibers to decrease the transmission of painful impulses. This is thought to occur through the gate control theory of pain or possibly through modulation of neurotransmitters in the central nervous system [34] (Fig. 105.3). A variety of surgical procedures for occipital neuralgia have been proposed, such as neurectomy, C1-C2 decompression, C2 ganglionectomy, and occipital nerve stimulation. The rate of meaningful pain relief from ganglionectomy has been reported to be 60% to 67% [35,36].

Surgical release of the inferior oblique muscles has been described as a potential treatment of occipital neuralgia, particularly when compression of the nerve by this muscle is suspected. In a small, retrospective study of 10 patients, the average visual analog score for pain decreased from 8 of 10 to 2 of 10 after the procedure [37]. Dorsal root entry zone lesioning has also been reported for occipital neuralgia [38].

Table 105.1 Pharmacologic Treatment of Occipital Neuralgia

Medication	Dosage	Common Side Effects
Nonsteroidal anti-inflammatory drugs	Variable	Gastrointestinal bleed, dyspepsia, nausea, headache, dizziness, rash, fluid retention, urticaria, hepatotoxicity, acute renal failure
Cyclooxygenase 2 inhibitors Celecoxib (Celebrex)	Celecoxib: 100mg bid or 200mg qd	Dyspepsia, nausea, abdominal pain, constipation, anorexia, elevated liver enzymes, acute renal failure, anaphylaxis, agranulocytosis
Tricyclic antidepressants Amitriptyline Nortriptyline Imipramine Carbamazepine (Tegretol)	Start at 10 mg qhs and titrate to 75 mg qhs or until clinical response	Dry mouth, constipation, urinary obstruction, sedation, postural hypertension, decreased seizure threshold
Gabapentin (Neurontin)	Start at 300 mg qd; titrate to 1200 mg tid	Sedation, unsteadiness, nausea, blurred vision, seizures, hepatitis, aplastic anemia
Mexiletine	Start at 150 mg qd × 3 d, then 300 mg qd × 3 d, then 10 mg/kg qd	Dyspepsia, dizziness, tremor, coordination problems, insomnia, diarrhea, palpitations, nervousness, headache, tinnitus, depression, rash, dry mouth, anorexia, fatigue, arrhythmia
		Somnolence, dizziness, ataxia, fatigue, nystagmus, tremor, blurred vision, myalgia, weight gain, nausea, amnesia, leukopenia

Potential Disease Complications

Occipital neuralgia is generally a self-limited disease, but it may progress in some cases to a chronic intractable pain syndrome. In refractory cases, it is critical to rule out more ominous conditions. Patients involved in litigation or who have psychosocial stresses or vocational disputes may have a poorer outcome.

Potential Treatment Complications

Nonsteroidal anti-inflammatory drugs have a number of well-established side effects, as do tricyclic antidepressants (Table 105.1). The anesthetic block of the greater or lesser occipital nerve is considered relatively safe [39]. Contraindications to this block include coagulopathy and current infection. Potential complications include bleeding, infection, nerve injury, seizure from intravascular injection of local anesthetic, and headache exacerbation. Care must be taken not to puncture the posterior occipital artery. If the artery is punctured, pressure should be applied vigorously.

Definition

Chronic pelvic pain (CPP), a common condition among women, affects up to one in four women of reproductive age at some point in their lifetime [1,2]. It can be an elusive disorder to diagnose and to treat, challenging even the most experienced clinicians. Despite variable opinions as to what constitutes this disorder, a widely accepted definition of CPP is noncyclic pain localized primarily in the anatomic pelvis, the anterior abdominal wall at or below the umbilicus, the lumbosacral spine, or the buttocks [3]. Traditionally, CPP must be of 6 months' duration and severe enough to cause functional disability or to require treatment. It can be of gynecologic, urologic, gastrointestinal, musculoskeletal, or neurologic etiology. The pain that arises from CPP can be categorized into somatic, visceral, neuropathic, or referred pain.

The prevalence of CPP is estimated to be 3.8% in women aged 15 to 73 years, similar to that of asthma, back pain, and migraine headaches. In primary care practices, it is estimated that 39% of women have complained of pelvic pain [1,2,4]. There are no known demographic factors—that put women at risk for development of CPP, although women with CPP tend to be of reproductive age.

Discovering the etiology of CPP (and therefore appropriate treatment) can be difficult because of the broad differential diagnoses and their many overlapping symptoms (see Table 106.1 for a complete list by organ system).

In addition, these diagnoses are not mutually exclusive but in many cases may coexist. For example, endometriosis and myofascial pain are often known to overlap. Because of the diagnostic complexity of CPP, an accurate diagnostic approach cannot always be assumed. This is especially true if medical or surgical therapies for discrete diagnoses have failed to provide relief.

The initial diagnostic approach should begin with a thorough history to narrow the differential diagnosis. The pain history should include pain characteristics such as first occurrence, location, duration, temporal pattern, precipitating and alleviating factors, relationship to urination and defecation, patterns of radiation, intensity, and effect of pain on life activities (such as activities of daily living, sleep, work, sexual intercourse, and social or recreational activities). A monthly pain calendar, which records episodes, location, severity, and associated factors, is useful to obtain accurate and detailed information. The history should also include prior treatments; history of substance abuse; history of sexual, physical, and psychological abuse; and thorough review of systems. A pain map of the body is a useful tool to help the physician and patient specify pain patterns. The usual components of a patient history, such as medical problems, previous surgeries, and reproductive history, should be included as well. To streamline the process of obtaining a history for patients with CPP, the International Pelvic Pain Society has created the Pelvic Pain Assessment Form, which is an excellent and freely reproducible tool that can be found on its website [5].

The most common causes of CPP are of gynecologic, gastrointestinal, urologic, and musculoskeletal origin and include specific diagnoses, such as endometriosis, chronic pelvic inflammatory disease (PID), irritable bowel syndrome, bladder pain syndrome, and myofascial pelvic pain [6].

Gynecologic

Endometriosis

Endometriosis is a common gynecologic condition affecting women of reproductive age. It is characterized by the presence of endometrial tissue (the inner layer of the uterus) outside of the uterus. The extrauterine endometrial implants respond to the hormonal stimuli in the same way as intrauterine endometrium does, causing cyclic bleeding in the sensitive tissues of the peritoneum, ovaries, fallopian tubes, and elsewhere. This process can lead to formation of pelvic adhesions, scar tissue, and endometriomas.

Table 106.1 Conditions Associated with Pelvic Pain in Women**Gynecologic**

Endometriosis*
 Chronic pelvic inflammatory disease*
 Pelvic adhesions
 Pelvic congestion (pelvic varicosities)
 Adenomyosis
 Ovarian remnant syndrome
 Residual ovary syndrome
 Leiomyoma
 Endosalpingiosis
 Neoplasia
 Fallopian tube prolapse (after hysterectomy)
 Tuberculous salpingitis
 Benign cystic mesothelioma
 Postoperative peritoneal cysts

Mental Health Issues

Somatization
 Substance abuse
 Physical and sexual abuse
 Depression
 Sleep disorders

Urinary Tract

Interstitial cystitis/painful bladder syndrome*
 Recurrent urinary tract infection
 Urethral diverticulum
 Chronic urethral syndrome
 Neoplasia
 Radiation cystitis

Gastrointestinal Tract

Irritable bowel syndrome*
 Inflammatory bowel disease and other causes of colitis
 Diverticular colitis
 Chronic intermittent bowel obstruction
 Neoplasia
 Chronic constipation
 Celiac disease (sprue)
 Chronic appendicitis

Musculoskeletal

Pelvic floor myalgia*
 Myofascial pain (trigger points)*
 Coccygodynia
 Piriformis syndrome
 Hernia
 Abnormal posture
 Fibromyalgia
 Peripartum pelvic pain syndrome

Neurologic Disorders

Neuralgia, especially of the iliohypogastric, ilioinguinal, genitofemoral, or pudendal nerves*
 Herniated nucleus pulposus
 Neoplasia
 Neuropathic pain
 Abdominal epilepsy
 Abdominal migraine

*These diagnoses are the most common causes of chronic pelvic pain and are backed by substantial evidence.

This disorder is found in 10% to 15% of women of reproductive age, in 25% to 40% of women undergoing treatment for infertility, and in 33% of women who have laparoscopy for CPP. Risk factors include early menarche, short menstrual cycles (less than 27 days), and müllerian anomalies that involve vaginal or uterine obstruction of blood flow. Symptoms include long-standing cyclic pelvic

pain, dysmenorrhea, menorrhagia, and deep dyspareunia. Severity of symptoms does not necessarily correlate with visual disease burden at time of surgery.

Uterine Leiomyomas

Leiomyomas (uterine fibroids, myomas) are benign smooth muscle tumors of the uterus and the most common neoplasm in women of reproductive age, with the highest prevalence in the fifth decade of life. The lifetime incidence of leiomyoma is 50% and up to 60% in women of African descent. Fibroids are thought to grow from estrogen stimulation. The most common symptoms are pressure from an enlarging pelvic mass, pain and dysmenorrhea, and abnormal uterine bleeding. The severity of symptoms is related to the size, number, and location of the tumors, although many women with fibroids are asymptomatic. In general, fibroids shrink after menopause. A myoma that grows rapidly after menopause is concerning for leiomyosarcoma, which occurs in 0.5% of fibroids.

Adenomyosis

Similar to endometriosis, adenomyosis is the presence of ectopic endometrial tissue in the myometrium (muscle layer) of the uterus. Adenomyosis develops from aberrant glands of the basalis layer of the endometrium and causes pain, dysmenorrhea, and menorrhagia. Some women experience intense pelvic cramping and pressure that radiates to the lower back, groin, rectum, and anterior thighs. Symptomatic adenomyosis usually is manifested in women aged 35 to 50 years, although adenomyosis can be found in asymptomatic women. The incidence of this disorder is unknown. As the ectopic endometrial tissue proliferates, the uterus takes on an enlarged, globular shape, which can sometimes be appreciated on examination.

Adhesive Disease

The correlation between abdominal adhesions and CPP is poorly understood, and studies of these are limited. It is thought that certain types of adhesions, particularly densely vascular adhesions to the bowel and peritoneum, cause CPP. Diagnosis can be made only at the time of laparoscopy as there are no examination findings, laboratory tests, or imaging studies that are reliably useful. Risk factors include a history of prior pelvic surgery, PID, endometriosis, inflammatory bowel disease, radiation therapy, and peritoneal dialysis.

Pelvic Congestion Syndrome

Pelvic congestion syndrome is a condition of vascular engorgement of the ovarian veins or internal iliac veins that leads to pelvic pain. Characteristic findings of gross dilation, incompetence, and reflux of the ovarian veins are seen on venography, sometimes forming parovarian pelvic varicosities. Dysfunction in the one-way valves of the ovarian veins is postulated as the underlying etiology. There is limited understanding of the prevalence of this condition as there are no definitive diagnostic criteria. As with most causes of pelvic pain, anatomic anomalies are not necessarily indicative of the presence or severity of pain. Pelvic congestion syndrome has been described only in premenopausal women. Typically, pain is worse after prolonged standing and improves in the morning after rest. Associated symptoms include marked ovarian tenderness, shifting location of pain, and deep dyspareunia or postcoital pain.

Chronic Pelvic Inflammatory Disease

PID starts as an acute condition and can become a chronic condition causing CPP. The transition from acute PID to chronic PID is incompletely understood and occurs in about 18% to 35% of women with acute PID. Women at risk for development of chronic PID include those who are not initially treated for the acute phase or are treated incompletely. In addition, the development of more severe adhesions or tubal damage and persistent pelvic tenderness 30 days after diagnosis and treatment increase the likelihood for development of CPP. Whether a woman is treated with an inpatient or outpatient regimen for acute PID does not have any bearing on the risk for later development of chronic PID or CPP [7]. Most PID is caused by *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Other implicated pathogens are *Gardnerella vaginalis*, *Haemophilus influenzae*, enteric gram-negative rods, and *Streptococcus agalactiae*. Diagnostic criteria and treatment of acute PID are published and maintained by the Centers for Disease Control and Prevention [8].

Gastrointestinal

Irritable bowel syndrome is a common functional bowel disorder of uncertain etiology characterized by a chronic, relapsing pattern of abdominopelvic pain and altered bowel habits in the absence of an organic cause. Although not all patients with this disorder seek treatment, the estimated prevalence is 10% to 15% in North America. The abdominal and pelvic pain is usually crampy in nature and varies in location, often exacerbated by emotional stress and eating habits and relieved by defecation. Patients also often complain of non-gastrointestinal symptoms, such as altered sexual function, dysmenorrhea, urinary frequency, or dyspareunia.

The Rome III criteria are used to diagnose irritable bowel syndrome, and patients must have two of the following: pain relieved with defecation; onset of pain associated with a change in frequency of stool; or onset associated with a change in form (appearance) of stool [9].

Urologic

Chronic bladder pain in the absence of other identifiable etiology has been termed bladder pain syndrome (BPS). Previously called interstitial cystitis (IC), this is actually a misnomer as there is no evidence of underlying evidence of inflammation. For historical reasons, the nomenclature has changed to IC/BPS. IC/BPS is characterized by suprapubic or urethral pain, pressure, or discomfort that is worse with bladder filling and relieved with voiding. The severity of symptoms ranges greatly and may vary from day to day. Other urinary symptoms, such as frequency, urgency, and nocturia, accompany the pain [10]. IC/BPS often coexists with other chronic pain syndromes, such as fibromyalgia, irritable bowel syndrome, or myofascial pelvic pain syndrome [11]. The underlying etiology has not been exactly elucidated but may be related to altered integrity of the glycosaminoglycan layer of the bladder.

Because IC/BPS is a clinical diagnosis, there are no characteristic laboratory or imaging findings. A voiding diary that logs fluid intake, voiding volume, and frequency demonstrates the characteristic frequent, low-volume voiding pattern.

Musculoskeletal

Myofascial pelvic pain is pain attributed to short, tight, and tender pelvic floor muscles scattered with characteristic trigger points, small hypersensitive areas within a tight band of muscle (Fig. 106.1). A trigger point can cause local pain and over time lead to regional and diffuse pelvic pain as well as visceral dysfunction, such as constipation or irritative voiding. The exact prevalence of myofascial pelvic pain syndrome is unknown. Determining if CPP is due to a myofascial etiology or caused by another disorder can be challenging. In fact, overlap between pelvic pain disorders is common. For instance, studies have shown that 70% of women with bladder pain syndrome also have myofascial pain, most often involving the levator ani muscles of the pelvic floor [12]. Myofascial pelvic pain is thought to originate from an abnormal response to muscle fiber trauma, causing peripheral and then central sensitization. Inflammatory mediators are released locally when a muscle is injured. Over time, the muscle nociceptors become conditioned to the stimulus and a lower response threshold to inflammatory mediators and mechanical stimulation ensues, leading to muscle hyperalgesia. Continued input from the injured or painful muscle leads to neuroplastic changes in the dorsal spinal cord, resulting in amplified pain to both noxious and non-noxious stimuli. Furthermore, secondary hyperalgesia develops such that pain is perceived outside of the original area of injury [12].

Physical, mechanical, systemic, and psychological factors have been associated with the development of trigger points. Physical factors include injury to the nerves and muscles at the time of childbirth or surgery. Mechanical factors that contribute to myofascial pelvic pain include abnormal posture, leg length discrepancy, gait disturbances, sacroiliac joint dysfunction, and diastasis recti, all of which can trigger asymmetric use of the levator muscles. Systemic factors such as subclinical hypothyroidism, nutritional inadequacies, chronic allergies, and impaired sleep have also been linked to the development and activation of trigger points.

With myofascial pelvic pain, patients often have difficulty in localizing pain. The pain is characterized as aching, throbbing, or pressure-like in quality. Myofascial pelvic pain can radiate to the hip or back and commonly worsens throughout the day, with bowel or bladder function, or after intercourse. During the examination, attention should be paid to the pelvic floor examination. Patients with myofascial pelvic pain will complain of pain when pressure is placed on myofascial trigger points, which are often found in the pubococcygeus and ileococcygeus muscles of the pelvic floor.

Symptoms

The specific symptoms of CPP vary greatly but are important to elicit because they can give diagnostic clues. Pain caused by endometriosis typically worsens premenstrually and throughout menses. Pain accompanied by symptoms of poor urinary flow, urinary hesitancy, or constipation suggests myofascial pelvic pain, pelvic floor muscle dysfunction, or an anatomic defect such as pelvic organ prolapse. Pain with radiation to the lower extremities may indicate myofascial pelvic pain, sacroiliac joint dysfunction, or spinal disease,

FIGURE 106.1 Myofascial pain involving the levator ani muscle of the pelvic floor. (From Waldman SD. *Atlas of Common Pain Syndromes*, 3rd ed. Philadelphia, WB Saunders, 2012.)

such as radiculopathy or cord compression. Improvement of pain while supine and aggravation of pain while upright suggest pelvic congestion syndrome. Lateralizing pain accompanied by hematuria may be indicative of urolithiasis or urinary tract obstruction. Crampy abdominal pain with diarrhea or constipation suggests irritable bowel syndrome or diverticular disease. Entry dyspareunia may be a symptom of lichen sclerosus, atrophic vaginitis, or vulvodynia; deep dyspareunia may be a symptom of endometriosis, myofascial pelvic pain syndrome, or chronic PID. Pain that increases with bladder filling and is associated with urinary frequency, nocturia, and painful voiding suggests IC/BPS.

Physical Examination

After a thorough history and review of systems, the clinician narrows the differential diagnosis. The goal of the physical examination is to reproduce, whenever possible, the patient's pain. Therefore it is important for the clinician to remember that this process can be a stressful and unpleasant experience for the patient. The physical examination—indeed, the entire evaluation—should be systematic and methodical. In the case of CPP, a multispecialty approach to both diagnosis and treatment is now considered standard of care. Therefore clinicians commonly treating patients with CPP should be familiar with the basic physical examination of the multiple organ systems around the pelvis that may give rise to pain symptoms. These clinicians ideally function

within a team of experts from various specialties to ensure a complete diagnostic approach.

After a screening examination of the lumbosacral spine is performed, the examination of the pelvis continues with the patient supine. The patient should be asked to identify the areas of most pain. A four-quadrant abdominal examination is then performed with superficial and deep palpation (ideally with the patient's abdomen relaxed), leaving the area of most pain until last, and taking note of discomfort, hernia, masses, and surgical scars. If hypersensitivity is found on the superficial examination, this can suggest myofascial trigger points. A simple maneuver, the Carnett test, can be used to differentiate myofascial pain from visceral abdominal pain. For the Carnett test to be performed, the area of pain on the abdomen is palpated with one or two digits, and then the patient voluntarily contracts the abdomen by raising legs and head off the table. If pain at the palpation site increases, this is likely a myofascial trigger point, and if pain decreases, it is likely visceral in origin.

The examination continues in the dorsal lithotomy position. The patient should again show the clinician where the area of most pain is. First, begin with examination of the external pelvis, looking at the groin, external genitalia, and perineum for asymmetry or dermatologic abnormality. The soft end of a cotton swab can be used to assess pain in the vestibule, posterior fourchette, and labia; if pain is present, it can be indicative of vulvodynia or vulvar skin disorders.

A lubricated single-digit examination of the pelvic floor is performed next, before placing a speculum or performing a bimanual examination, which can aggravate the muscles of the pelvic floor. The base of the pelvic floor is palpated and the vagina should feel like a soft cylinder. In patients with hypertonic disorders, a shelf of contracted musculature can usually be felt in addition to myofascial trigger points. Myofascial trigger points are small areas of contracted tissue that are exquisitely tender on palpation and produce either direct or referred pain. The bladder base, cul-de-sacs, cervix, uterus, and adnexa should then be palpated, again noting tenderness, symmetry, and fullness, which can be indicative of endometriosis or pelvic masses.

The final part of the genitourinary examination is the speculum examination. A small speculum is suggested as a larger one can be difficult to pass into the vagina if there is pain and discomfort. The clinician should again note symmetry of the position of the cervix; shortening of the uterosacral ligaments causes lateral displacement of the cervix and is a classic finding of endometriosis. Vaginal and cervical culture specimens are obtained as indicated, particularly if chronic PID is suspected. Vaginal atrophy, seen in postmenopausal women with loss of vaginal rugae and lightening of the normal lush pink hue of the vaginal walls, can cause discomfort and is easily treated with vaginal estrogen.

Functional Limitations

CPP frequently results in significant functional limitations. In general, patients with chronic pain syndromes may have psychological distress because of delayed diagnosis and treatment. Chronic unrelieved pain is known to contribute to anxiety, depression, sleep disturbance, and altered family and social roles that may have an impact on all areas of function. Pelvic floor muscle myofascial pain may increase with prolonged sitting or standing, which may limit the patient's ability to participate in work, social, and recreational activities. In addition, bowel and bladder function may be affected, and in some cases incontinence may result. Many patients with CPP also complain of dyspareunia interfering with normal sexual function.

Diagnostic Studies

In the evaluation of CPP, history and physical examination are the mainstays of diagnosis, although several studies may help narrow the differential or confirm or exclude a specific diagnosis. In general, the most useful imaging modality for pelvic organs is ultrasonography, which can detect uterine fibroids, intrauterine disease, adnexal disease (e.g., endometrioma, ovarian neoplasm), and adenomyosis. Magnetic resonance imaging is preferable to assess adenomyosis. If there is a high suspicion for pelvic congestion syndrome, pelvic venography can be performed. Although there are no imaging studies that are useful in the diagnosis of myofascial pelvic pain syndrome, surface electromyography can provide objective evidence of muscle dysfunction.

Laboratory evaluation can include urine analysis and culture, sexually transmitted infection testing, complete blood count, erythrocyte sedimentation rate, or thyroid assay as indicated by the patient's risk factors and comorbid conditions. Results of laboratory tests, such as CA-125, can be

elevated in the presence of endometriosis, but the sensitivity and specificity are too low to be of clinical value. When urinary symptoms are present, a urine analysis should be performed to rule out underlying infection, and patients with hematuria should be evaluated with cystoscopy.

Laparoscopy can be used as an extension of the diagnostic regimen. In fact, 40% of all laparoscopies are performed for CPP. When laparoscopy is performed for CPP, 33% of women are found to have endometriosis, 24% are found to have adhesive disease, and 35% have no visible disease [13]. Biopsy of any pathologic process found on laparoscopy is important because visual diagnosis of endometriosis is often unreliable. Diagnostic laparoscopy has the benefit of offering simultaneous treatment; if endometriosis or pelvic adhesions are found during the operation, ablation or resection can be performed. Patients who present with gastrointestinal symptoms should be referred to a gastroenterologist and will likely undergo colonoscopy as part of the evaluation.

Differential Diagnosis

- Endometriosis
- Pelvic inflammatory disease
- Pelvic adhesions
- Pelvic varicosities
- Adenomyosis
- Ovarian remnant syndrome
- Leiomyoma
- Endosalpingiosis
- Neoplasia
- Fallopian tube prolapse
- Tuberculous salpingitis
- Recurrent urinary tract infection
- Urethral diverticulum
- Inflammatory bowel disease
- Diverticulitis
- Bowel obstruction
- Chronic constipation
- Celiac disease
- Chronic appendicitis
- Coccygodynia
- Piriformis syndrome
- Hernia
- Fibromyalgia
- Iliohypogastric, ilioinguinal, genitofemoral, or pudendal neuralgia
- Herniated nucleus pulposus

Treatment

Initial

Establishing a patient-physician relationship based on trust and confidence is important in treating CPP. During the arduous diagnostic process, concern for the patient should be expressed and her symptoms validated. As with any chronic pain condition, it is important to discuss expectations of symptom improvement and management. Treatment of CPP is a process that often requires time and a multimodality approach to treatment involving primary care providers, physicians from an array of specialties, and physical therapy.

While the patient is going through the diagnostic process, it is reasonable to start empirical treatment based on

diagnostic probability. When a specific diagnosis is made, targeted therapy should be initiated. A 4- to 6-week trial of maximum-strength nonsteroidal anti-inflammatory drugs (NSAIDs) is an appropriate first-line therapy. If this is ineffective, a second NSAID may be tried because of variable responses of patients to individual drugs.

In addition to NSAIDs, when a gynecologic etiology is likely, hormonal therapy may be started either sequentially or simultaneously. Oral contraceptive pills should be attempted for two or three cycles, prescribed either in the standard manner or continuously. If the combination of NSAIDs and continuous oral contraceptive pills is unsuccessful after 2 to 3 months, second-line agents may be tried; these include progestins and gonadotropin-releasing hormone (GnRH) agonists.

Initial treatment of mild irritable bowel syndrome involves patient education, dietary modification, and behavioral changes. If patients have moderate or severe symptoms, pharmacologic agents may be added.

With IC/BPS, a stepwise approach should be taken for treatment; it may begin with simple measures such as heat or cold to the suprapubic area, avoidance of food or activities that exacerbate pain, and fluid management. Bladder analgesics, such as phenazopyridine or methenamine, may be used initially. For longer term management, non-narcotic and narcotic pain medications can be used, guided by principles used to manage other chronic pain conditions. Intravesical instillation of lidocaine with heparin or sodium bicarbonate may be used to manage pain exacerbations.

Some women find relief of CPP symptoms from complementary and alternative medical treatments, such as acupuncture, acupressure, and nutritional supplements. The decision to pursue these modalities should be individualized as there is a paucity of high-quality studies in the medical literature.

Endometriosis

Treatment of women with presumed or proven endometriosis usually begins with NSAIDs for pain management and combined oral contraceptive pills to induce a relative hypoestrogenic state, thereby decreasing the proliferation of extrauterine endometrial tissue. Long-acting progestones, such as intramuscular medroxyprogesterone, etonogestrel subdermal implant, or levonorgestrel intrauterine device, are also useful in achieving a hypoestrogenic state. If these first-line therapies fail, GnRH agonists or aromatase inhibitors can be used [6]. If medical therapy fails, laparoscopy can be used to reduce disease burden, or the uterus and ovaries can be removed [13].

Uterine Leiomyomas

In women with fibroids, treatment should be guided by severity of symptoms, nearness to menopause, and desire for childbearing potential. A GnRH agonist, such as intramuscular leuprolide, can be used to help shrink the fibroid burden, although its side effect profile is onerous for some women. Uterine artery embolization, myomectomy (either hysteroscopically or abdominally), and hysterectomy are other treatments. Pregnancy should be avoided after uterine artery embolization, and a cesarean section is usually recommended in the case of pregnancy after myomectomy. If a woman is near menopause and has mild or moderate

symptoms, it is reasonable to treat with NSAIDs and to re-evaluate after menopause.

Myofascial Pelvic Pain Syndrome

Treatment of myofascial pelvic pain is best done with a multidisciplinary approach. Myofascial pelvic pain is often associated with other diagnoses, such as irritable bowel syndrome, endometriosis, depression, constipation, painful bladder syndrome, and chronic urinary tract infections. It is critical to treat a concomitant diagnosis if one is found because that may be the very thing that incites or exacerbates the myofascial pain. Neurogenic pain may be treated with tricyclic antidepressants or γ -aminobutyric acid analogues (such as gabapentin or pregabalin). However, the mainstay for treatment of myofascial pelvic pain is pelvic floor physical therapy, and specific techniques for physical therapists have been well described.

Rehabilitation

A comprehensive, multidisciplinary approach in managing CPP is of the utmost importance, and physical therapy plays an integral role in this. Physical therapists evaluate the structural, biomechanical, postural, functional, musculoskeletal, and neurologic dysfunctions that may cause, perpetuate, or result from pelvic pain. Involving the physical therapist in the early stage of pelvic pain is highly recommended. Rehabilitative interventions include connective tissue manipulation; behavioral retraining and education for posture, activity, and bowel and bladder habits; therapeutic exercise; neuromuscular reeducation; and manual therapy techniques for joints, soft tissue, and fascia [14]. Physical therapy appears to be most successful when all of these elements are considered and positive findings are addressed through a progressive and individualized treatment program.

Procedures

In the case of myofascial pelvic pain syndrome, patients who improve incompletely with physical therapy may benefit from trigger point injections into the pelvic floor muscles. Trigger point injections are most often performed with local anesthetic, such as lidocaine or bupivacaine [15]. Botulinum toxin A injections have also been used to reduce CPP and pelvic floor muscle spasm [16]. Sacral neuromodulation is an additional treatment option for women with myofascial pelvic pain and has been used in the treatment of refractory, nonobstructive urinary retention, urinary frequency or urgency, and urge incontinence. Although it is not approved by the Food and Drug Administration for the treatment of IC/BPS or pelvic pain, some studies suggest a benefit for these conditions [17].

Surgery

If medical therapy fails to bring improvement, diagnostic and potentially therapeutic laparoscopy should be pursued. Laparoscopic adhesiolysis can temporarily alleviate symptoms due to pelvic adhesions; however, adhesions often tend to recur rapidly. The role of hysterectomy in idiopathic CPP is controversial as there is a failure rate of pain resolution of 40%. In addition, there is an unclear understanding of which

patients benefit from hysterectomy and which do not [18]. In the case of adenomyosis, hysterectomy is considered the definitive treatment for those who fail to respond to medical management. Other surgical procedures for CPP, such as presacral neurectomy and uterosacral nerve ablation, offer limited improvement in symptoms and are usually no longer performed.

Potential Disease Complications

If it is left untreated, CPP has the potential to cause severe debilitation, both from a personal standpoint and from a societal standpoint. Lessening of quality of life, depression, lost wages, and lack of participation in society can have long-reaching consequences.

Potential Treatment Complications

Potential adverse effects of NSAIDs are well publicized and include gastritis, gastrointestinal ulcers, renal impairment, and cardiac morbidity. GnRH agonists carry risk of early osteoporosis. Complications due to invasive procedures include bleeding and infection.

997.60 Stump (surgical) (post-traumatic), abnormal, painful, or with complication (late)

ICD-10 Code

G54.6 Phantom limb syndrome with pain

Definition

Phantom pain refers to a painful sensation perceived in a body part that is no longer present subsequent to surgical or traumatic removal. It is most common after the amputation of a limb (i.e., phantom limb pain), but it has also been reported after the surgical removal of other body parts, such as breast, rectum, penis, testicles, eye, tooth, tongue, or lesion of peripheral or central nervous system [1]. Phantom limb pain is distinguished from stump pain, which is pain in the residual limb or stump, and phantom limb sensation, which is a nonpainful sensation of the absent part. Peripheral, spinal segmental, central, and psychological mechanisms are considered factors in the development of phantom limb pain, and an increasing number of studies with functional neuroimaging have suggested a central mechanism for phantom limb pain [2–5].

Although phantom limb pain is generally present within the first few days after an amputation, it can take several

months or years to emerge. The reported prevalence of phantom limb pain differs considerably, ranging from about 40% to 90% [1,6]. However, phantom limb pain is less frequent in congenital amputation and loss of a limb early in childhood. The occurrence of phantom limb pain is independent of gender, age (in adults), level or side of amputation, dominance, and etiology of amputation.

In several reports, the intensity of pain remained constant but both the frequency and duration of pain attacks decreased significantly over time [7,8]. A small percentage of patients experienced a reduction in intensity of pain over time. Phantom limb pain leads to permanent disability in more than 40% of amputees, and pain persisting for more than 6 months is exceedingly difficult to treat.

Phantom limb pain has been reported to be significantly related to residual limb pain, physical activity, severity and duration of preamputation pain, noxious intraoperative inputs (such as pain brought about by cutting of tissues), acute postoperative pain, bilateral amputation, and lower limb amputation.

Symptoms

Pain is most prominent immediately after the operation; it is not static in nature and changes in quality over the years. Phantom limb pain is usually intermittent, but some patients report constant pain with superimposed exacerbations. The duration of an attack ranges from seconds or minutes to hours or days. Phantom limb pain is usually localized in distal parts of the absent limb, usually in the foot or hand.

The pain can be described as tingling, throbbing, aching, pins and needles, squeezing, stabbing, shooting, pinching, or cramping. Sometimes, the patients report that the amputated limb is positioned in a painful posture or that they sense spasms in the limb. The intensity as well as the quality of the pain varies greatly among patients from mild to severe. Phantom limb pain is triggered or worsened by physical (e.g., rainy weather, low temperature, prosthetic use, urination, defecation, reduced blood flow, and muscle tension), psychosocial (e.g., attention), and emotional (e.g., anxiety and stress) stimuli. Phantom limb pain is not relieved with position.

Physical Examination

Physical examination is generally unrevealing. However, patients can sometimes identify specific points on the

residual limb that trigger phantom limb pain. Therefore the residual limb should be assessed for any sources of pain or trigger areas. The residual limb is examined for neuromas, cysts, bursae, bone spurs, or sites of excessive pressure. Other precipitating factors should be searched for, such as an ill-fitting prosthesis or mechanical stimulation.

Local problems, such as a herniated disc or spinal disease emitting sensations into the phantom limb or neuroma, can cause neuropathic pain. A comprehensive physical evaluation with particular attention to the neurologic examination, including strength, range of motion, muscle stretch reflexes, and muscle tone, should be done to rule out any concomitant central or peripheral neuropathic pain.

Functional Limitations

Functional complications of phantom limb pain include sleep disorders, interference with prosthesis training and use, reduction in walking ability, inability to return to work, change in employment status, and limitation of participation in social activities. Patients with phantom limb pain experience a greater degree of despair, more symptoms of depression, less satisfaction with social relations, poorer psychosocial adjustment, and poorer quality of life than amputees who are unaffected [9].

Diagnostic Studies

The diagnosis of phantom limb pain is generally made clinically on the basis of history and physical examination. Plain radiography and ultrasonography are performed for the diagnosis of underlying conditions, such as neuroma, abscess, bursitis, bone spur or fragment, or nerve entrapment. Magnetic resonance imaging, electrophysiologic tests, or laboratory tests may be indicated if other diagnoses are suspected.

Nerve block may be attempted as a diagnostic tool to identify candidates for specific procedures. Various pain scales and psychometric questionnaires are used to assess severity, treatment effect, and disability.

Deep brain stimulation
Cortical resection of brain

Other

Acupuncture

fitting process should be carefully reviewed with the patient. Preemptive analgesia in an attempt to prevent phantom limb pain by epidural or general routes during the preoperative and initial postoperative period has not been shown to be effective. Compression stockings or stump shrinkers during the early postoperative period can also be helpful.

Tricyclic antidepressants and anticonvulsants have long been considered to be the drugs of choice [1]. Controlled studies, however, showed conflicting data on the effect of tricyclic antidepressants in phantom limb pain [10,11]. Anticonvulsants such as carbamazepine, gabapentin, topiramate, and lamotrigine are effective.

Randomized controlled studies have demonstrated that opioids have analgesic efficacy in phantom limb pain and suggest an effect on cortical reorganization [12–14]. Morphine is effective in decreasing pain intensity in the short term [15]. Tramadol is an analgesic with both monoaminergic and opioid activity that is effective in long-standing phantom limb pain.

N-Methyl-D-aspartate (NMDA) receptor antagonists, such as ketamine and dextromethorphan, showed efficacy in controlling phantom limb pain [15,16].

Other pharmacologic interventions, such as beta blockers, topical capsaicin, nonsteroidal anti-inflammatory drugs, nonopioid analgesics, and botulinum toxin, have been suggested, but well-controlled trials have not been published.

Rehabilitation

Transcutaneous electrical nerve stimulation has long been considered an effective treatment modality; it can begin early in the postoperative period without significant side effects. However, a recent Cochrane review failed to find sufficient evidence to support the effectiveness of transcutaneous electrical nerve stimulation for phantom limb pain [17]. Heat and cold, manipulation, vibration, massage, and acupuncture can all be tried, but there is no evidence of their efficacy.

Several studies have reported positive results of biofeedback, including electromyographic biofeedback, thermal biofeedback, and muscle relaxation procedures [1,18]. Use of a prosthesis that provides sensory, visual, and motor feedback reportedly reduces phantom limb pain [19,20]. Sensory discrimination training or tactile stimulation has also been reported to reduce phantom limb pain with a reversal of cortical reorganization. Mirror therapy and motor imagery have been shown to decrease phantom limb pain, supporting a central mechanism for the presence of pain [2,4,21–23].

Psychological interventions such as relaxation technique, stress management, distraction, and hypnosis can also provide relief, although very few specific studies of patients with phantom limb pain were conducted.

Procedures

Regional anesthesia with local anesthetics, including plexus or nerve block, sympathetic block, and epidural block, can be applied to intractable phantom limb pain. A continuous perineural infusion of a local anesthetic was reported to be effective in preventing and decreasing phantom limb pain [24].

Surgery

Surgery is generally not indicated for phantom limb pain. Stump revision, such as neuroma resection, is indicated in selected patients with stump pain due to neuroma. The purpose of neuroma resection is relief of stump pain, not of phantom limb pain.

Spinal cord stimulation, dorsal root entry zone ablation, neurectomy, sympathectomy, dorsal rhizotomy, cordotomy, thalamotomy, and cortical resection of brain have been used in a few cases of intractable pain [25,26].

Potential Disease Complications

Phantom limb pain may cause significant disability. It keeps amputees from their usual activities and causes considerable interference with their daily, social, recreational, and work activities. The health-related quality of life of amputees

with phantom limb pain is poorer than that of amputees without phantom limb pain.

Potential Treatment Complications

Side effects of pharmacologic treatment are well documented. Complications of regional anesthesia are systemic effects of local anesthetics, physiologic effects of the procedure (e.g., hypotension, inadvertent injection or block), and damage to adjacent structures. Spinal cord stimulation has few serious complications. Complications of surgical ablation techniques include Horner syndrome, dysesthesia, sudomotor paralysis, weakness, urinary complications, and respiratory problems. Selection of appropriate patients is important to successful surgical ablation.

ICD-10 Codes

B02.22 Postherpetic trigeminal neuralgia
B02.29 Postherpetic nervous system involvement

Definition

Varicella-zoster virus is a lipid-enveloped, double-stranded DNA herpesvirus that coevolved with ancestral primates for more than 70 million years [1]. It expresses its genes sequentially, leading to expression of nonstructural proteins, nonstructural protein enzymes, and late structural proteins [2]. Late structural proteins encapsulate the DNA core, infect host cells, and replicate in host cell nuclei.

Acute varicella-zoster infection is the initial activation of the virus manifested with a diffuse pruritic, vesicular rash. This is commonly known as chickenpox. Two viremic phases are thought to occur in acute zoster infection. Animal studies suggest that the first viremia occurs in regional lymph nodes and viscera, approximately 5 days after exposure [3]. The second viremia, approximately 14 days after exposure, promotes viral spread to the nasopharynx and the skin, causing the hallmark rash [4]. The virus usually infects children and spreads by aerosol droplets and skin-to-skin exposure to the vesicles, which contain large amounts of virus.

Herpes zoster, or shingles, is the reactivation of latent varicella-zoster virus. After acute herpes zoster infection, the virus remains dormant and resides in sensory ganglia, including the dorsal roots and cranial nerves [5]. Reactivation generally results from immunocompromised states such as stress, disease, or advanced age. The virus typically migrates along dermatomes, manifesting as a painful rash. The virus may spread to the spinal sensory nerves, dorsal horn, or cranial nerves. It is a painful condition with a highly age-related incidence, affecting about 50% of individuals who survive to the age of 85 years [6]. It affects men and women equally. Involvement of motor nerves is extremely rare.

Postherpetic neuralgia is pain persisting in affected dermatomes despite resolution of the rash. Although the timeline may be variable, many define postherpetic neuralgia as persistent pain 4 months or more after resolution of acute herpes zoster [7]. The likelihood for development of postherpetic neuralgia increases with older age, female sex, presence of a prodrome, greater rash severity, and greater acute pain severity [8]. It is the most common complication after an acute episode of shingles.

Symptoms

Prodromal symptoms may precede varicella-zoster reactivation by a few days up to 1 week. These include low-grade fever and malaise with hyperesthesia, dysesthesia, paresthesia, or pruritus along the distribution of affected dermatomes.

Fulminant shingles is marked by the emergence of erythematous macules accompanied by severe burning, stinging pain in a single sensory or cranial nerve distribution. This is followed by the eruption of fluid-filled papules, clusters, and vesicles. New skin eruptions generally continue to appear for 3 to 5 days. Thoracic dermatomes are most frequently affected. During this period, prodromal low-grade fever and malaise may continue to persist, and lymphadenopathy may also be present.

Zoster affecting exposed areas may result in sun or wind sensitivity. Sensitivity to light touch, intolerance to wearing of clothes over the erupted area, and brief jolts of shooting pain are also common.

Of the cranial nerves, the ophthalmic branch of the trigeminal nerve is the most often affected. If there is ophthalmic involvement, photophobia may be present. This is

known as herpes zoster ophthalmicus and can result in monocular blindness. It has an incidence of 1% in the general population [9].

In very rare cases, zoster of the geniculate ganglion occurs, affecting the seventh and eighth cranial nerves. Symptoms include otalgia, vertigo, tinnitus, ataxia, loss of hearing, loss of taste, and even ipsilateral facial paralysis. This is known as Ramsay Hunt syndrome (herpes zoster oticus).

In most cases, symptoms tend to resolve shortly after healing of the rash. However, in more than 25% of patients, neuralgia persists for longer than 1 month after resolution of the rash [10]. This pain is commonly described as sharp, burning, aching, or shooting and may be accompanied by allodynia and hyperalgesia.

Physical Examination

In shingles, typical skin eruptions follow a dermatomal distribution, appearing as raised, fluid-filled vesicles. Once the vesicles burst and release fluid that contains live virus, they crust. Once the vesicles have crusted, the patient is no longer infectious. Lesions are often exquisitely tender to light touch. If deeper dermal involvement is present, scarring and discoloration may be seen.

Ophthalmic zoster is usually accompanied by a rash in the dermatomal distribution of the nasociliary nerve, along the side of the nose (Hutchinson sign). Periorbital edema, petechial hemorrhages, conjunctivitis, scleritis, and corneal sensitivity are also commonly associated with ophthalmic zoster [9]. Hutchinson sign and an unexplained red eye are indications for ophthalmologic consultation.

Ramsay Hunt syndrome is manifested as a rash on the auricle and external ear accompanied by exquisite otalgia, vestibulocochlear dysfunction, and facial nerve palsy. Any suspicion for Ramsay Hunt syndrome should lead to an urgent otolaryngology consultation.

With postherpetic neuralgia, there are no visible skin abnormalities on inspection. However, the patient may describe allodynia or hyperalgesia on even very gentle palpation.

Functional Limitations

Functional limitations due to herpes zoster include difficulty with activities involving pressure or heat exposure to the affected area. If the facial divisions of the trigeminal nerve or areas by the ear are affected, individuals may not tolerate wearing of protective headgear or facemasks and facial exposure to sun or wind. If the thoracic dermatomes are affected, clothing or even touching of the back against an office chair may increase pain. Both sex and contact sports may be intolerable. Difficulty in sleeping may arise from discomfort from sheets touching the skin. Bathing and towel drying often exacerbate pain along the affected dermatome.

If the optic nerve or the ophthalmic branch to the trigeminal nerve is affected by shingles, monocular low vision may result in impaired depth perception and decreased field of view. If the patient has herpes zoster oticus, hearing, balance, tasting, and facial muscle movements are impaired. Thus, driving may be affected by zoster involvement of the trigeminal nerve or the geniculate ganglion.

Diagnostic Studies

Zoster is usually easy to diagnose on the basis of history and physical examination. In general, laboratory tests for diagnosis of reactivation of herpes zoster virus are not clinically useful [11]. For atypical cases, the Centers for Disease Control and Prevention guidelines suggest direct fluorescent antibody testing for rapid diagnosis [10]. To obtain a specimen, apply a sterile cotton swab to the base of an open lesion or, less preferably, a lesion crust.

Differential Diagnosis

- Complex regional pain syndrome
- Contact dermatitis
- Drug-related allergic infection
- Eczema
- Other herpetic neuralgias
- Nonherpetic viral infection
- Radiculitis
- Tertiary syphilis

Treatment

Initial

Prevention is important in this condition. Varicella vaccination in childhood is primary prevention for chickenpox. Zoster vaccination, recommended by the Centers for Disease Control and Prevention and the Advisory Committee on Immunization Practices for people 60 years of age or older [12], prevents herpes zoster reactivation as shingles. In a randomized double-blind placebo-controlled trial of the zoster vaccine, there was reduction of herpes zoster incidence by 51.3% and postherpetic neuralgia incidence by 66.5% [13]. However, there is still insufficient evidence for vaccination in the long-term prevention of postherpetic neuralgia [14].

If given within 72 hours of symptom onset, antiviral medication with oral acyclovir, valacyclovir, or famciclovir has been shown to relieve acute zoster pain and shorten rash duration, although there is no consistent evidence that it reduces the incidence of postherpetic neuralgia [15].

For patients with immunocompromise or malabsorption, the intravenous route of antiviral medication delivery is preferred to the oral route. There is limited evidence that a course of intravenous followed by oral antiviral treatment reduces pain in patients with postherpetic neuralgia of more than 3 months' duration [19].

Topical therapies that are approved by the Food and Drug Administration for postherpetic neuralgia include lidocaine and capsaicin. Lidocaine is available both as a 5% patch and in a gel cream form. A double-blind placebo-controlled efficacy and safety study with lidocaine patch has shown improvements in pain, allodynia, quality of life, and sleep measures [20,21].

Topical capsaicin is an extract of hot chili peppers that works as an agonist of the vanilloid receptor TRPV1. Capsaicin is available as an 8% patch and as different cream formulations. A small randomized double-blind controlled study with capsaicin showed a decrease in the numerical pain rating scale scores of patients by 33.8% compared with

a 4.9% increase in controls [22]. Application of capsaicin should lead to desensitization of the unmyelinated epidermal nerve fibers and reduced hyperalgesia with repeated applications.

Other topical treatments that have been studied include topical aspirin, indomethacin, and diclofenac [23]. These have not been well studied and are not widely used in clinical practice.

Oral medications effective in treating postherpetic neuralgia include antiepileptic drugs, antidepressants, and opioid analgesics. The anticonvulsants gabapentin and pregabalin are approved by the Food and Drug Administration for treatment of postherpetic neuralgia. Both gabapentin and pregabalin are calcium channel ligands. Gabapentin can provide statistically significant improvement in daily pain rating, sleep, mood, and quality of life for patients with postherpetic neuralgia [24,25]. Pregabalin acts like gabapentin and is similarly useful in postherpetic neuralgia [26–28].

Whereas amitriptyline has been most studied, secondary amine tricyclics such as nortriptyline are usually preferred because of the side effect profile [28–30].

Use of opioids and opioid-like analgesics including tramadol, oxycodone, morphine, and methadone can also reduce severe pain in postherpetic neuralgia [31–33]. Use of opioids and opioid-like analgesics requires caution and close monitoring for side effects and medication abuse.

There are a number of guidelines for treatment of postherpetic neuralgia, with slight variations in recommended protocols [10,34,35]. Most would consider topical lidocaine, tricyclic antidepressants, and gabapentin or pregabalin first-line agents. Topical capsaicin, tramadol, and opioid analgesics are second- or third-line therapies [34,35]. Combination therapy may provide superior pain management while minimizing medication side effects [36,37].

Rehabilitation

Ultrasound may be effective in relieving acute zoster pain. In a clinical trial of acute zoster pain, more than 80% of participants receiving ultrasound were pain free at the end of the treatment compared with 46% in the placebo group [38]. The treatment parameters used in areas adjacent to the vertebral column were 1 MHz frequency, 25% pulsed cycle, applied for 1 minute per effective radiating area of the transducer at 0.8 W/cm² intensity and around the periphery of the vesicles at 0.5 W/cm².

Transcutaneous electrical nerve stimulation (TENS) is a widely used nonpharmacologic treatment thought to reduce nociception from small delta fibers and nonmyelinated fibers by stimulating larger, myelinated afferent nerve fibers, although its exact mechanism of action is still not well understood [39]. When TENS was applied to the second digit compared with the third and fifth digits in patients with carpal tunnel syndrome, fMRI showed temporarily decreased pain-related cortical activation [40]. When applied to the superficial radial nerve in healthy volunteers, TENS was found to increase the heat pain threshold [40a]. In a small RCT, patients with postherpetic neuralgia receiving a combination of TENS and oral pregabalin reported superior pain relief compared with those receiving a combination of sham TENS and pregabalin [40b]. In another combination therapy RCT, patients with postherpetic neuralgia reported

significant pain reduction from baseline after receiving 8 weeks of TENS combined with local cobalamin injection [40c]. In summary, although there is theoretical support for TENS as a treatment for neuropathic pain and it has been recently studied in combination with other drugs, there is a need for studies comparing TENS alone against placebo in patients with postherpetic neuralgia. Although there is no consensus about voltage, pulse duration, or pulse frequency, TENS is thought to be most effective when applied at the maximum setting that is not uncomfortable.

Desensitizing treatments, such as alternating exposure to heat and cold, vibration, and repeated light tapping of the affected area, may be helpful but are not well studied.

In cases of ophthalmic involvement, occupational therapists can instruct in scanning techniques for low vision and decreased peripheral vision. If the geniculate ganglion is affected, occupational therapists may work on techniques for hearing impairment or vestibulocochlear dysfunction. Occupational therapists can also assist with fall risk reduction, such as by removal of loose rugs, improvement in lighting, and decrease of clutter in the home and work environment.

Other practical measures to improve function include rearrangement of workstations to reduce contact of sensitive areas with seat backs and armrests, use of low-friction fabrics such as silk, use of a hand-held showerhead to direct water flow away from painful dermatomes, and modification of sexual positions.

Procedures

Subcutaneous botulinum toxin injection has been successful in relieving postherpetic neuralgia pain in two small randomized, double-blind, placebo-controlled studies [41,42]. One study not only showed decreased pain, but patients who received botulinum toxin also had improved sleep and reduced opioid use compared with subcutaneous 0.5% lidocaine and placebo with 0.9% saline [42].

Retrospective studies on the effect of sympathetic nerve blocks have reported reduced duration of acute herpes zoster pain as well as short-term improvement with postherpetic neuralgia. However, the long-term effect of sympathetic nerve block in postherpetic neuralgia has not been established [43, 43a].

Paravertebral injection of bupivacaine and methylprednisolone may be helpful as adjuvant therapy to conservative management. A randomized study of 132 herpes zoster patients compared standard therapy of oral antivirals and analgesics or standard therapy with adjuvant paravertebral injections. The incidence of postherpetic neuralgia was 2% in the intervention group compared with 16% with standard treatment [44].

Epidural injection of steroids may provide modest, short-term pain relief in postherpetic neuralgia. In a randomized, controlled trial of 598 patients receiving standard oral antiviral and analgesic therapy with and without epidural steroid injection, the injection of bupivacaine and methylprednisolone was found to have a modest effect in reducing the pain of postherpetic neuralgia for 1 month but did not prevent long-term postherpetic neuralgia [45].

Intrathecal administration of methylprednisolone and lidocaine has led to significant decrease in pain intensity and

area in a randomized trial of 277 patients with intractable postherpetic neuralgia. Patients in the intrathecal steroid group also had decrease in nonsteroidal anti-inflammatory drug use [46].

Other interventions, such as greater occipital nerve block, deep cervical nerve blocks, stellate ganglion blocks, and Jaipur block with subcutaneous lidocaine, bupivacaine, and methylprednisolone, have occasionally improved symptoms in case reports and observational studies [47–50]. The effects of cryotherapy, percutaneous nerve stimulation, and radiofrequency have not been well established. Spinal cord stimulation may be of benefit in medically complicated patients with multiple drug sensitivities, polypharmacy, and serious comorbid conditions [51]. Although these interventions have not been adequately studied, they may have some efficacy in treatment of recalcitrant postherpetic neuralgia symptoms.

Surgery

Surgery is not indicated for postherpetic neuralgia.

Potential Disease Complications

Acute optic neuritis from ophthalmic zoster may lead to permanent loss of vision, usually due to virus-induced impairment in retinal perfusion, leading to retinal necrosis. Retinal necrosis generally occurs in severely immunocompromised patients [52].

Herpes zoster ophthalmicus has also been associated with orbital apex syndrome, an inflammation of the oculomotor nerve thought to be related to secondary vasculitis within the orbital apex. This syndrome can cause impaired eye motility and often is manifested as dysconjugate gaze and diplopia.

Similarly, Ramsay Hunt syndrome may lead to permanent facial nerve paralysis and vestibulocochlear dysfunction.

Potential Treatment Complications

Topical lidocaine is generally well tolerated with only mild to moderate localized skin reactions reported [21]. However, topical capsaicin may cause greater local skin reaction including redness, burning pain, and itching [22].

The most common side effects of gabapentin and pregabalin are dizziness and somnolence. All tricyclic antidepressants may cause fatigue or sedation, dizziness, dry mouth, blurry vision, constipation, urinary retention, orthostatic hypotension, and QT prolongation or cardiac arrhythmias. Side effects of opioids and opioid-like analgesics include typical narcotic medication adverse effects of nausea, diarrhea, and constipation.

Gastrointestinal, hepatic, and renal complications may arise from prolonged use of acetaminophen, antiviral medications, or nonsteroidal anti-inflammatory drugs.

All interventional procedures carry a risk of pain, infection, and bleeding. Sympathetic nerve blocks may also cause hypotension, bradycardia, unintentional motor blockade, and neuropathic deafferentation pain. Epidural injections and paravertebral injection may result in hematoma or abscess formation. Complications of intrathecal methylprednisolone include hypotension, nerve root irritation, arachnoiditis, transverse myelitis, and chemical meningitis.

Spinal cord stimulation adverse effects include infection, dural puncture, pain from stimulator component, equipment failure, and dislocation. These may require reoperation or removal procedures.

I89.0 Lymphedema, not elsewhere classified
G89.28 Chronic postoperative pain

Definition

Post-mastectomy pain syndrome (PMPS) is a chronic pain condition, typically neuropathic in nature, that can follow surgery to the breast [1]. PMPS can occur with any surgery to the breast including mastectomy, lumpectomy, reconstruction, and augmentation, although symptoms of post-mastectomy pain are reduced with sentinel lymph node procedures [2,3]. PMPS affects approximately 40% to 52% of patients after breast surgery [3–5]. The risk factors for development of PMPS include younger age, more extensive surgery, more than 15 lymph nodes removed, more immediate postoperative pain, and anxiety [2,4,6]. Within the first 24 hours of surgery, 60% of patients have severe pain [7]. PMPS typically is manifested as phantom breast pain, intercostobrachial neuropathy, or incisional pain. Early management includes pain control, desensitization techniques, and shoulder range of motion. Chronic management includes neuropathic pain agents, interventional procedures, and rehabilitation. Primary objectives of management include sleep preservation, maintenance of shoulder function, and vocational rehabilitation.

Classification of PMPS can be divided into four categories: phantom breast pain, intercostobrachial neuralgia, myogenic pain, and neuroma pain [8]. Phantom pain is identified

in 23% of post-mastectomy patients and consists of painful sensations in the area of the removed breast [9]. The intercostobrachial nerve is the lateral cutaneous nerve of the second thoracic root. It courses along the axillary vein and then provides sensation to the axilla and breast (Fig. 109.1). The intercostobrachial nerve is frequently stretched or sacrificed during axillary lymph node dissections and is a common cause of PMPS [8,10,11]. Myogenic pain is common after mastectomy and is associated with surgical irritation and immobilization. The scar from breast surgery can be a generator of pain. The pain has been attributed to underlying neuroma formation, axon impingement, and scar retraction [8,12].

Symptoms

The symptoms associated with PMPS include shooting, stabbing, burning, and pins and needles sensations in the breast, axilla, or medial arm [1,3,8,13–15]. In addition, patients complain of symptoms of tightness and fullness in the axilla. Pain is aggravated by shoulder movement, stretching, straining, and direct contact with clothes [3,13]. The symptoms of PMPS are usually nonprogressive and have been found to persist in half of patients observed for 9 years [1,13]. PMPS results in functional loss and sleep disruption, and these may be common presenting complaints [1,12].

Physical Examination

The primary aspects of the physical examination include exclusion of other causes of the identified pain and classification of PMPS. General inspection should be performed to evaluate for muscle wasting, asymmetry, and gross masses. The musculoskeletal examination should focus on shoulder range and function; muscle restriction in the pectoralis major and minor; and costovertebral, costochondral, and rib integrity. A careful skin examination should be performed to assess for scar adherence, fibrosis, scar tenderness, neuromas, infection, and recurrence of malignant disease. The lymphatic examination should be performed to assess for lymphadenopathy in lymphatic distributions not already dissected. The neurologic examination includes motor testing of the shoulder girdle, focusing on motor nerves potentially affected by breast surgery (thoracodorsal, long thoracic, medial and lateral pectoral). Sensory testing should include all breast dermatomes T1–T5. Particular attention should

FIGURE 109.1 Regional anatomy relevant to post-mastectomy pain.

be paid to the posterior thorax dermatome as this can be a clue to spinal disease. The sensory examination of the axilla should identify the distribution, severity, and type of sensory abnormality. The complete neurologic examination should include a full assessment of ipsilateral upper extremity motor, reflex, and sensory function.

Functional Limitations

The major functional limitations with PMPS include loss of shoulder range of motion, lifting restrictions, and sleep disruption. Loss of shoulder range of motion is attributed to maintenance of the more comfortable adducted position, resulting in restricted abduction and external rotation [13]. Concurrently, restriction in the pectoralis minor and major results in decreased forward flexion and extension. Limitations with lifting result in diminished capacity to perform household duties (vacuuming, laundry), occupational duties (stocking shelves), and vocational pursuits [1,12,13]. Sleep disruption affects 50% of patients with PMPS and can lead to global daytime dysfunction [13].

Diagnostic Studies

Diagnostic studies are used primarily to exclude other causes of pain. Recurrent malignant neoplasms can be excluded by mammography, magnetic resonance imaging, or positron emission tomography scans. Dedicated imaging of the thoracic spine is warranted to exclude other suspected causes of neuropathic pain in the breast dermatomes, such as radiculopathy. Electrodiagnosis can be useful to exclude motor nerve abnormalities and plexopathy.

Differential Diagnosis

- Tumor recurrence
- Rib fracture
- Paraneoplastic neuropathy
- Intraparenchymal lung disease
- Chemotherapy neuropathy
- Thoracic nerve root impingement
- Radiation plexopathy
- Intercostal neuralgia

Treatment

Initial

The initial management of PMPS commences perioperatively. This includes minimizing dissection, nerve-sparing procedures, and early pain control. Early pain control is imperative because severe early postoperative pain is one of the most consistent factors in PMPS [5,7]. Early postoperative pain control is typically accomplished with judicious use of opiates and nonsteroidal anti-inflammatory drugs. A study found pregabalin in a single 75-mg dose preoperatively and 12 hours postoperatively to reduce pain [16]. Early desensitization techniques can help limit neuropathic symptoms and can be initiated once the incision is healed. For those with uncontrolled pain that limits sleep and daily function, neuropathic pain medications can be initiated. Some pharmaceuticals, such as capsaicin, amitriptyline, nortriptyline, gabapentin, pregabalin, and lidocaine patches, have been studied and found to be effective [8,14,16,17]. Long-acting opiates can be used when these agents fail to control symptoms [14].

Rehabilitation

From a rehabilitation perspective, PMPS management begins immediately postoperatively. The primary factor for rehabilitation management is to identify functional limits. Clearly, shoulder restriction is a major factor in the functional limitations from PMPS. Shoulder rehabilitation begins with stretching of the pectoralis complex and latissimus dorsi followed by glenohumeral range of motion and finally scapulohumeral retraining. Upper extremity strengthening commences once full shoulder range of motion is obtained. Targeted muscle groups for weight training include the latissimus dorsi, trapezius, scapular stabilizers, rotator cuff, and deltoid. Weight training should be performed with low weights and high repetitions. The final phase of rehabilitation is task-specific training, progressing from basic activities of daily living to household tasks, work-related duties, and recreational pursuits. It is important to guide the breast cancer survivor through resumption of full activity to avoid unnecessary injury.

Procedures

Procedural management of PMPS is typically limited to regional nerve blocks for pain control [14]. For those with progressive shoulder dysfunction and painful range of motion, local injections in the subacromial space may be beneficial. In addition, myofascial injections with anesthetic preparations or botulinum toxin can be beneficial for myogenic pain.

Surgery

Surgical management of PMPS typically relates to chest wall pain or shoulder dysfunction. Chest wall pain with scar retraction can be managed with scar removal. In addition, soft tissue adherence to chest wall structures may require surgical repair. Adhesive capsulitis as a result of progressive loss of shoulder range of motion may require manipulation under anesthesia for full shoulder range of motion to be obtained.

Potential Disease Complications

The primary potential disease complications from PMPS include adhesive capsulitis, loss of shoulder function, and diminished carrying capacity of the affected extremity. Resultant to this lack of function, patients can lose employment and vocational and recreational capacity. An insidious and life-altering complication of PMPS is sleep disruption. Sleep disruption can result in global dysfunction and health-related complications.

Potential Treatment Complications

Treatment complications are primarily related to side effects from medications. Capsaicin is known to cause painful skin reactions by its mechanism of action. Tricyclic antidepressants have anticholinergic side effects and must be used with caution in patients with cardiac arrhythmias. The main side effects of gabapentin include sedation, tremors, and dizziness. Topical lidocaine patches can result in skin excoriation. Bleeding, infection, and nerve irritation can complicate interventional procedures. Surgical procedures including manipulation under anesthesia and scar removal can result in increased pain and secondary soft tissue restriction.

CHAPTER 110

Post-Thoracotomy Pain Syndrome

Justin Riutta, MD, FAAPMR

Synonym

None

ICD-9 Code

338.22 Chronic post-thoracotomy pain

ICD-10 Code

G89.22 Chronic post-thoracotomy pain

Definition

Post-thoracotomy pain syndrome (PTPS) is pain that recurs or persists at the incision site or in the dermatomal distribution of the intercostal nerves for longer than 2 months after thoracotomy [1–3]. Thoracotomies are used to access intrathoracic contents, such as the lung, esophagus, and heart. The most common indication for a thoracotomy is tumor resection. The classic thoracotomy consists of a posterolateral incision of the thorax, bisection of the latissimus dorsi and serratus anterior, separation of the ribs, disruption of the intercostal nerves, and pleural incision. The thoracotomy is regarded as one of the most painful surgical procedures performed [1–10]. The incidence of PTPS has a wide range (2% to 90%), but on average, approximately 40% of patients will have chronic postoperative pain [2,4]. PTPS is mild to moderate in 92% of cases; 50% of patients will have disruption in the capacity to perform daily activities. Sleep disruption occurs in 25% to 30%. Fortunately, severe disabling pain occurs in only 3% to 5% of patients with PTPS [5,6]. Predictive factors for development of PTPS include increased pain 24 hours postoperatively, female gender, preoperative opiate use, and radiation therapy [4,8].

Intercostal neuralgia is the most commonly implicated cause of chronic PTPS [1]. Other factors contributing to pain are outlined in Table 110.1. Recognizing that local muscle disruption of the serratus anterior and latissimus

dorsi results in abnormal scapulohumeral mechanics, shoulder abnormalities are one of the common causes of functional loss after thoracotomy [7].

Symptoms

PTPS generally is manifested with symptoms of allodynia, dysesthesias, and lancinating pain typically attributed to intercostal neuralgia [4]. In addition, patients will have symptoms of achiness, pleuritic pain, and focal tenderness over the incision site [1,4]. Shoulder movement, deep breathing, and lying directly on the affected side can aggravate these symptoms [4]. Pain is frequently encountered with shoulder maneuvers and direct contact with the incision site and can be manifested as shoulder dysfunction and sleep disruption.

Physical Examination

The examination of the patient with PTPS includes inspection of the incision site and chest wall movement with respiratory excursion. Deep breathing maneuvers to elicit pleuritic pain are another component of the examination. Palpation over the incision site to evaluate for scar adherence, hypersensitivity, or intercostal nerve pain is the next component of the examination. The rib cage is disrupted with surgery and must be assessed for persistent fractures, costochondral avulsions, and costochondritis. Assessment of regional musculature for postoperative disruption, atrophy, and myofascial pain is important. Adhesive capsulitis and shoulder girdle dysfunction are factors in PTPS; therefore active and passive range of motion of the shoulder and scapulohumeral mechanics should be evaluated. Neurologic examination includes motor testing of the affected extremity compared with the unaffected side, evaluation for scapular winging, and assessment of the dermatomal distribution of the transected intercostal nerves.

Functional Limitations

PTPS results in daily activity limitations in 50% of those affected [5]. Ochroch and associates [9] identified functional decrement using the 36-item short form health survey (SF-36) in most patients at 4 to 48 weeks postoperatively. Shoulder restriction secondary to chest wall pain, adhesive capsulitis, and disruption of the serratus anterior and latissimus dorsi has been identified in 15% to 33% of post-thoracotomy patients

Table 110.1 Factors Associated with Post-Thoracotomy Pain [1,4]

Intercostal neuroma
Rib fracture
Adhesive capsulitis
Infection
Pleurisy
Costochondral dislocation
Costochondritis
Local tumor recurrence
Myofascial pain
Vertebral collapse

at 1 year [7]. Shoulder restriction leads to limitations in sleep function, lifting capacity, and full range of motion activities of the shoulder girdle. In addition, functional limitations can be attributed to respiratory compromise related to surgery or underlying pulmonary disease.

Diagnostic Studies

The relevant diagnostic studies include baseline radiographs of the rib cage to evaluate for bone disruption. In addition, chest radiographs and computed tomography scans can be used to screen for intrathoracic processes, such as pleura-based dysfunction, pneumonia, and recurrence of primary malignant disease. A diagnostic intercostal nerve block can be performed to identify intercostal neuralgia.

Differential Diagnosis

Rib fracture
Costochondral dislocation
Vertebral collapse
Adhesive capsulitis
Costochondritis
Pleurisy
Myofascial pain
Muscle disruption pain
Tumor recurrence
Thoracic radiculopathy
Intercostal neuroma
Cardiac ischemia
Aortic dissection
Infection of incision, pleura, pleural space, and lung parenchyma

TREATMENT

Initial

The initial treatment of PTPS includes early aggressive management of pain. Preemptive analgesia is the concept of diminishing postoperative pain by disrupting pain pathways preoperatively [1]. Aspects of preemptive analgesia include thoracic epidural anesthesia, intercostal nerve blockade, opiates, and nonsteroidal anti-inflammatory drugs (NSAIDs) [1]. Thoracic epidural anesthesia has been shown to diminish acute postoperative pain in thoracotomy [10]. Balanced anesthesia with preoperative regional anesthesia, opiates, and NSAIDs diminishes the incidence of PTPS from 50% to 9.9% [2,4]. The surgical approach does have a bearing on postoperative pain. Smaller surgical incisions

and muscle-sparing thoracotomies diminish postoperative pain [1]. In addition, early removal of chest tubes has been associated with diminished pain and improved pulmonary function [11].

Acute postoperative pain management includes thoracic epidural administration of opiates in combination with regional anesthesia and NSAIDs. Opiates alone decrease the incidence of PTPS to 23.4% [12]. In addition, opiates plus regional anesthesia decrease the incidence of PTPS to 14.8%. The opiates, anesthesia, and NSAIDs combine to diminish PTPS rates to 9.9% [12]. Further, early scar management, once healing is complete, can diminish long-term pain by reducing adhesions to chest wall structures and diminishing hypersensitivity. The primary technique to do this is gentle massage and repetitive stimulation of the incision site. Transcutaneous electrical nerve stimulation units have also been found to be effective in reducing PTPS [13,14].

Pharmacologic management of PTPS includes early postoperative use of opiates and NSAIDs in combination [2]. Delivery of topical anesthetics by patches (lidocaine) also can be used for pain control [2]. Management of chronic PTPS is usually through use of neuropathic pain medications. The only study specifically for PTPS used gabapentin and found that this was well tolerated and decreased pain in 73% of those studied; 42% of those studied had more than 50% pain relief [15]. Neuropathic pain medications used in other conditions that have not been studied in PTPS include amitriptyline and nortriptyline. If oral routes of pain control fail, intrathecal administration of opiates is an option.

Rehabilitation

The preoperative management of PTPS begins with nutritional assessment and augmentation. Patients with intrathoracic disease can frequently encounter nutritional issues as a result of their primary disease; it can be beneficial for postoperative recovery to maximize nutritional status. The second factor in preoperative management is to maintain or to obtain normal shoulder range of motion. As mentioned, shoulder dysfunction and muscle dysfunction occur in up to 33% of thoracotomy patients. Maximization of range, function, and muscle strength before surgery can reduce functional loss secondary to postoperative restriction.

Pulmonary rehabilitation is important in thoracotomy patients primarily because many have underlying pulmonary disease. Pulmonary rehabilitation preoperatively includes breathing techniques, energy conservation, instruction in medication use, secretion management, and aerobic endurance training. The objective is to reduce frequently encountered postoperative complications secondary to decreased depth of breathing, retention of secretions, atelectasis, and pneumonia [10]. Pulmonary rehabilitation begins postoperatively with breathing techniques, secretion management, and assisted coughing with stabilization of the disrupted thorax.

Scar mobilization is an important aspect of early pain relief. Scars can increase pain secondary to adherence to chest wall structures, underlying nerve entrapment, and restriction of range of motion of the shoulder. Early scar mobilization consists of gentle massage to maintain mobility of the

incision and the soft tissue structures adjacent to the incision. Soft tissue massage techniques are not initiated until adequate wound healing has occurred.

Shoulder dysfunction is a common sequela of PTPS. The shoulder dysfunction has multiple factors, including muscle disruption, chest wall pain with shoulder movement, and myofascial pain. Surgical disruption of the latissimus dorsi and serratus anterior can lead directly to shoulder dysfunction. The serratus anterior stabilizes the scapula against the chest wall and aids in protraction. Normal shoulder abduction is limited without serratus anterior function. The latissimus dorsi is a powerful adductor of the arm. Latissimus dorsi restriction can lead to lack of forward flexion and abduction at the glenohumeral joint. The disruption of these two muscle groups is less of an issue with muscle-sparing procedures. The rehabilitation process is delayed primarily because of time for muscle continuity to return after disruption. The initial management includes gentle massage of the affected muscle group and pendulum exercises. This is followed by gentle active range of motion exercises that progress to passive range of motion exercises once full muscle continuity has been regained. Strengthening is the next process and can take up to a full year. Weakness in the latissimus muscle group may persist and requires attention and appropriate restrictions. The primary issue with the serratus anterior is obtaining normal scapular mechanics and normalizing scapulohumeral rhythm. This may require dedicated physical therapy by a therapist who understands shoulder mechanics. Shoulder rehabilitation may be delayed by postoperative restrictions. The standard restrictions are active range of motion only and no lifting of more than 10 pounds. These restrictions as standard practice are in place for 6 weeks after surgery. Full lifting as tolerated is typically not recommended until 12 weeks after surgery.

The next step in rehabilitation is regaining and perhaps surpassing of presurgical function with endurance training. Endurance training can include low-impact lower extremity exercise, such as walking and stationary biking once pain allows. The patient can progress to high-load activities (e.g., running, swimming, climbing) after full healing of the chest wall, typically at 12 weeks. The final step is return to work and vocational rehabilitation. It is important to address goals of the rehabilitation process early in management; this helps both the physiatrist and patient to set goals that will maximize quality of life.

Procedures

Management of PTPS with interventional procedures consists of perioperative and chronic pain management. As mentioned, the perioperative management involves preemptive analgesia with regional anesthesia preoperatively [2,4]. Thoracic epidural anesthesia is the primary means of early postoperative management, and this typically consists of infusion of an opiate and an anesthetic [1]. Chronic PTPS management usually starts with intercostal nerve blockade [2]. Thoracic nerve root block and radiofrequency ablation of intercostal nerves are other procedures used for PTPS [2]. Long-term maintenance pain management can be accomplished with intrathecal opiate delivery and spinal cord stimulators [2].

Surgery

There are no surgical treatments for post-thoracotomy pain.

Potential Disease Complications

The potential complications of PTPS include postoperative respiratory dysfunction secondary to decreased depth of breathing, retention of secretions, and atelectasis [10]. In addition, persistent chest wall pain can result in decreased shoulder movement and adhesive capsulitis. Shoulder function also may be affected by the disruption of the serratus anterior and the latissimus dorsi, resulting in scapular dysfunction and glenohumeral dysfunction, respectively. In addition, sleep disruption, depression, loss of employment, and diminished functional and vocational capacities can be seen in PTPS.

Potential Treatment Complications

Complications of PTPS treatment include local complications from interventional procedures, including hematomas, infections, and nerve disruption. In addition, the use of opiates and NSAIDs postoperatively can lead to gastrointestinal dysfunction. The most common side effects identified with the use of gabapentin in this population are sedation (24%) and dizziness (6%) [13].

Definition

Radiation-induced toxicity after cancer treatment may result in significant long-term disability. Radiation fibrosis describes the insidious pathologic fibrotic tissue sclerosis that occurs in response to radiation exposure. Radiation fibrosis syndrome (RFS) is the term used to describe the myriad clinical manifestations of progressive fibrotic tissue sclerosis that can result from radiation treatment. It is estimated that about half of the approximately 14 million cancer survivors in the United States will receive radiation treatment during the course of their disease [1]. The incidence of RFS is unknown, and its severity is affected by multiple factors (see later). Radiotherapy is typically combined with surgery or chemotherapy; therefore the toxicities of these modalities may be cumulative and difficult to separate clinically.

The therapeutic goal of radiation therapy is to kill rapidly proliferating tumor cells by inducing apoptosis or mitotic cell death through free radical-mediated DNA damage [2].

Various dose-sculpting techniques have been developed to minimize exposure to normal tissues; however, radiation exposure to normal body cells cannot be completely eliminated [3]. The effects of radiation can be acute (occurring during or immediately after treatment), early-delayed (up to 3 months after completion of treatment), or late-delayed (occurring more than 3 months after completion of treatment) [4]. Radiation fibrosis is generally a late complication of radiation therapy and may become clinically apparent many years after treatment. Its progression can be insidious or rapid, but it is invariably irreversible [5,6]. It can damage any tissue type, including skin, muscle, ligament, tendon, nerve, viscera, and bone [7]. The underlying mechanism of radiation fibrosis is complex and not completely understood. It has been postulated that radiation-induced vascular endothelial injury causes thrombomodulin deficiency, resulting in its inability to scavenge locally formed thrombin, which in turn leads to abnormal accumulation of proliferative fibrin in the intravascular, perivascular, and extravascular compartments [2].

The long-term morbidity due to RFS is largely determined by the size of the radiation field, the type and susceptibility of underlying tissues to radiation, and the patient's individual resistance to the effects of radiation. Other factors include the patient's age, overall health, and medical and degenerative disorders, particularly degenerative spine disease; cancer status; exposure to neurotoxic, cardiotoxic, and other chemotherapy types; and time since radiation was administered [8]. For signs or symptoms to be considered referable to RFS, either the structures generating them must be within the radiation field or the neural, vascular, lymphatic, muscular, tendinous, or other structures important in their genesis must traverse the field. It is therefore necessary to understand which type of radiation field was used to treat a given patient to determine whether the signs, symptoms, or functional deficits can be attributable to RFS. The common radiation fields used in Hodgkin lymphoma (HL) are depicted in Figure 111.1. Extensive radiation fields, such as mantle field used to treat HL, can result in widespread sequelae of RFS. Patients with head and neck cancer (HNC) treated with radiation are also likely to develop RFS because of the high dose of radiation required for tumor control as well as the proximity of many vital tissues to the radiation field [9].

FIGURE 111.1 Radiation fields used to treat Hodgkin lymphoma. These fields encompass a vast amount of normal tissue and are well known to cause marked adverse late effects, particularly in patients treated with high doses in the mid-1980s.

Symptoms

Patients with RFS can present with a variety of symptoms as virtually every organ system can be affected. Symptoms should be anatomically congruent to the radiation field and involved tissues. HL survivors frequently present with neck extensor weakness (dropped head syndrome), pain and limited range of motion of the neck and shoulders, weakness, fatigue, gait and dexterity problems, neuropathic symptoms, and difficulty in performing activities of daily living. Spasms are frequently described as tight, pulling, or cramping sensations. Neuropathic pain is usually described as burning, stabbing, or searing. HNC patients commonly have trismus, cervical dystonia, facial lymphedema, dysphagia, and dysarthria. Radiation-induced trigeminal neuralgia (commonly in the V2-V3 distribution on the affected side, but bilateral involvement is possible) and anterior cervical neuralgia are also common complications. Neuropathic pain in patients with RFS can be severe and markedly out of proportion to the perceived pathologic process. If the spinal cord was in the radiation field, patients may present with spastic paraparesis or quadriparesis, depending on the level of the spinal cord affected by radiation. Early-delayed radiation-induced myelopathy is almost always reversible, whereas late-delayed is almost always progressive and permanent [10]. If autonomic nerves are affected, patients can present with orthostatic hypotension, baroreceptor failure, bowel and bladder

dysfunction, and sexual dysfunction. Shortness of breath in HL patients treated with mantle field radiation may be due to pulmonary insufficiency from bilateral phrenic nerve dysfunction [11].

Physical Examination

Comprehensive examination, including detailed neuromuscular and musculoskeletal evaluation, is of paramount importance. Physical examination findings will vary greatly from patient to patient; however, a full account of physical examination findings is beyond the scope of this chapter.

Examination of patients treated for HL commonly demonstrates cervicothoracic paraspinal, shoulder girdle, and rhomboid muscle atrophy and often a C-shaped posture due to forwardly positioned neck and shoulders secondary to relatively strong pectoral muscles (Fig. 111.2). HNC patients commonly present with asymmetric positioning of the head and neck due to severe neck tightness, pain, and spasms of trapezius, sternocleidomastoid, and scalene muscles, among others. This radiation-induced cervical dystonia may progress to fixed contracture of the anterior cervical musculature [12]. Trismus seen in HNC patients is commonly associated with spasms in the masseter and pterygoid muscles (Fig. 111.3). Marked loss of range of motion and function may be seen if joints were involved in the radiation field. Rotator cuff tendinitis

FIGURE 111.2 Typical pattern of C-shaped posture (**A**) and cervico-thoracic muscle atrophy (**B**) in a Hodgkin lymphoma patient previously treated with mantle field radiation.

FIGURE 111.3 Severe trismus in a patient with tonsillar cancer treated with high-dose radiation. The patient is actively trying to open his mouth but has no clearance between his front teeth. He must ingest predominantly liquid nutrition between his back teeth. Oral hygiene and surveillance for recurrent cancer, among other functions, are severely compromised by his limited mouth opening.

and adhesive capsulitis may develop because of perturbation of normal shoulder motion secondary to C5 and C6 radiculopathy or upper brachial plexopathy [13]. Neurologic testing may reveal sensory loss, including light touch, pain, temperature, vibration, and proprioception.

Weakness and gait dysfunction may be secondary to damage of neural tissue (spinal cord, plexus, cauda equina, peripheral nerves) or muscle itself. Not infrequently, the clinical picture fits that of myelo-radiculo-plexo-neuromyopathy, with some or all components of the neuromuscular axis affected to varying degrees. The upper brachial plexus, frequently included in the radiation field of head and neck radiation ports, may be more susceptible to radiation injury because of its apical location in the neck and the long course traversed by its fibers relative to the middle and lower trunk. The pyramidal shape of the thorax and the clavicle may provide less protective tissue around the upper plexus, but the clinical validity of this phenomenon is unclear [14].

Functional Limitations

Sensory loss, pain, and weakness may have profound effects on gait and ability to perform activities of daily living. Loss of sensation also renders the patient more susceptible to secondary musculoskeletal injuries. Patients with severe trismus may have deficits including but not limited to difficulty in speaking, eating, drinking, and performing oral hygiene. Inability to position the head due to progressive fibrosis and contracture of the anterior cervical musculature can also affect swallowing, phonation, and work-related tasks. Patients with neck extensor weakness frequently have to stop driving and limit their work and leisure activities. Disability may also be related to bowel, bladder, and sexual dysfunction.

Diagnostic Studies

Imaging is often useful in the evaluation of RFS. A baseline magnetic resonance imaging (MRI) study of the entire spine for HL patients with RFS and of the cervical spine for HNC patients is often indicated to exclude degenerative processes of the spine or secondary malignant neoplasms. The addition of gadolinium contrast is required to exclude brain metastasis, intramedullary spinal tumor, or leptomeningeal disease and to differentiate tumor from scarring or fibrotic tissue in patients with a history of prior surgery. In addition, MRI of the spine may demonstrate overt demyelinating lesions or nodular enhancement of the cauda equina mimicking leptomeningeal disease in some patients treated for HL with high-dose radiation (Fig. 111.4). Computed tomography (CT) with contrast enhancement is used to evaluate the viscera of the chest, abdomen, and pelvis for metastatic or progressive disease. CT may also be used if MRI is contraindicated (because of a pacemaker, aneurysm clips, or breast tissue expanders, for example). CT myelography is indicated when metallic hardware causes excessive artifact, precluding adequate visualization of the spinal canal. Radiography is useful to evaluate suspected loosening or failure of spinal stabilization hardware or joint replacement prostheses.

Electrodiagnostic evaluation may provide invaluable information by identifying, localizing, confirming, or differentiating radiculopathy, plexopathy, neuropathy, or myopathy in patients with RFS. Needle electromyography can confirm muscle denervation and may identify myokymia, fasciculations, and muscle spasms. Given the

FIGURE 111.4 Gadolinium-enhanced T1-weighted magnetic resonance image depicting cauda equina enhancement (arrow) in a Hodgkin lymphoma patient who previously received periaortic radiation therapy.

high likelihood of multiple overlapping disorders present on electrodiagnostic testing, these studies should be interpreted by electromyographers with considerable experience in the evaluation of complex neuromuscular disorders.

Differential Diagnosis

FACIAL PAIN

Trigeminal neuralgia
Temporomandibular joint disorder
Trismus

NECK PAIN

Cervical dystonia
Spinal accessory mononeuropathy
Anterior cervical plexus neuralgia
Dropped head syndrome
Myofascial pain

SHOULDER PAIN

Rotator cuff tendinitis
Adhesive capsulitis
C5 or C6 cervical radiculopathy
Upper trunk brachial plexopathy

EXTREMITY PAIN AND WEAKNESS

Myelopathy
Radiculopathy
Plexopathy
Neuropathy
 Mononeuropathy
 Polyneuropathy
Myopathy
Tumor or neoplasm
 Primary
 Recurrent
Funicular pain
Musculoskeletal disorders
Fibromyalgia
Aromatase inhibitor-induced arthralgia or myalgia

Treatment

Initial

Whereas there is no cure for or way to stop progression of fibrotic tissue sclerosis leading to RFS, the patient's symptoms and function are likely to improve with appropriate treatment. Treatment is geared specifically toward the patient's complaints and functional deficits. Specialized care and a multidisciplinary approach are critical to successful rehabilitation. Patient education with an emphasis on the benefits of a lifelong home exercise program is of paramount importance. Many patients, especially HL survivors, require physical, occupational, and lymphedema therapy. The goals of physical therapy are to restore muscle balance and to correct the posture and body mechanics by stretching tight structures, strengthening weak musculature (core and neck extensors), and improving proprioception and endurance. Physical and occupational therapy are critical elements to rehabilitation of HNC patients with trismus and cervical dystonia. Patients with trismus also benefit from speech and swallowing therapy.

Rehabilitation

Orthotic devices are prescribed according to the principles used in other neuromuscular and musculoskeletal disorders, regardless of the underlying cause. Patients with weak neck extensors may benefit from a cervical collar, such as the Headmaster Collar (Symmetric Designs, Salt Spring Island, British Columbia, Canada). It is intended only for intermittent use and serves as an energy conservation device. Upper extremity orthotic devices may be appropriate in select patients with severe radiculopathy or plexopathy but are infrequently used. Lower extremity orthotic devices, such as ankle-foot orthoses, may be used for patients with a footdrop from any cause, including myelopathy, radiculopathy (usually L4-L5), plexopathy (lumbosacral trunk), and neuropathy (sciatic, common peroneal [fibular], deep peroneal [fibular] nerves). A posterior leaf spring ankle-foot orthosis is the most commonly used as it is lighter and less bulky than the alternatives. Patients with excessive spasticity (rarely seen in RFS unless myelopathy predominates) or significant mediolateral ankle instability require a custom molded ankle-foot orthosis. Control of the knee to prevent buckling is sometimes indicated. Patients with weak quadriceps may develop compensatory genu recurvatum, which may result in knee pain and degeneration. Older patients and those with weakness affecting multiple joints may benefit from a knee immobilizer. If weakness of both knee extension and ankle dorsiflexion is present, a knee immobilizer can often be fabricated to fit in a modular fashion over an ankle-foot orthosis and tends to be easier to manipulate than a knee-ankle-foot-orthosis.

Medications are often needed to control pain and muscle spasms in RFS. For the pain to be effectively managed, one must determine whether the pain is neuropathic or musculoskeletal (somatic) in nature. In many patients, both neuropathic and somatic pain may coexist. Neuropathic pain and, to some extent, muscle spasms associated with RFS may respond to nerve stabilizing agents. Pregabalin (Lyrica) is preferred to gabapentin (Neurontin), given its favorable pharmacokinetics, efficacy, and low potential for

drug-drug interaction [15]. Duloxetine (Cymbalta) is also a suitable agent for neuropathic pain in RFS and can be used in conjunction with pregabalin. Duloxetine, as a serotonin and norepinephrine reuptake inhibitor, may adversely interact with other serotonin reuptake inhibitors and should generally be avoided with tricyclic antidepressants, tramadol, and triptans. Opioids are often added to pregabalin or duloxetine when needed but should be considered second-line agents. Tricyclic antidepressants might be helpful in neuropathic pain, but their unfavorable side effect profile (anticholinergic effects resulting in dry mouth, blurred vision, constipation, urinary retention, arrhythmia, drowsiness, orthostatic hypotension, sexual dysfunction) limits their use. A short course of a nonsteroidal anti-inflammatory drug (NSAID), especially during acute exacerbation of symptoms, may be used to control somatic pain from inflammation of the rotator cuff, adhesive capsulitis, and other underlying degenerative changes. Long-term use of NSAIDs is relatively contraindicated, given their known gastrointestinal and cardiovascular side effects, particularly in the HL survivor population, who are at increased risk. Opioids are often used to control somatic pain when NSAIDs are ineffective or contraindicated. Muscle relaxants, including baclofen, tizanidine (Zanaflex), and benzodiazepines, may help relieve pain associated with muscle spasms but should be discontinued if deemed ineffective after a short trial.

Patients with trismus should be evaluated for a jaw stretching device. In the first 6 months of treatment, the TheraBite Jaw Motion Rehabilitation System (Atos Medical Inc., West Allis, Wisconsin) may be used. The Dynasplint Trismus System (Dynasplint, Severna Park, Maryland) is generally preferred in patients with chronic trismus because it is customizable and uses the principle of low-torque, prolonged duration stretch, which may be more effective at improving range of motion in an experimental model [16].

Procedures

Trigger point injections and botulinum toxin injections are of particular benefit in specific conditions associated with RFS [17]. Trigger point injections may provide significant pain relief for up to 1 month and should be offered to patients with painful muscle spasms in the trapezius, levator scapulae, rhomboids, cervical paraspinal, and other muscles. Usually, 2 to 5 mL of 0.25% bupivacaine or a similar anesthetic is used per location, up to a maximum of 20 mL divided between one and ten sites. Botulinum toxin injections may be used as both primary and adjunctive treatment for musculoskeletal pain, muscle spasms, spasticity, migraines, neuropathic pain, and a variety of other disorders [18]. Some studied cancer-related indications for botulinum toxin injections include chronic and neuropathic pain after neck dissection, muscle spasms after radiation therapy to the head and neck, and radiation-induced trismus [12,19,20].

Patients with RFS-related neuromuscular and musculoskeletal pain who fail to respond to conservative management may also benefit from interventional procedures, including epidural steroid injections, peripheral nerve blocks, and intra-articular joint injections. Placement of

implantable epidural drug pumps is usually discouraged because it would preclude patients from undergoing MRI in the future, which might be needed for disease surveillance.

Surgery

In general, conservative measures are the mainstay of treatment because surgery is unlikely to improve the marked and progressive neuromuscular disorders due to RFS. Severe dysfunction and atrophy of the underlying neuromuscular structures confer poor surgical outcomes. Coronoidectomy may be considered in a patient with severe trismus for whom conservative management failed, although clinical evidence for its efficacy is limited [21].

Potential Disease Complications

The clinical complications of RFS vary greatly and depend on multiple factors, as discussed earlier. Multiple non-neuromuscular complications (e.g., fatigue, alopecia, lymphedema, esophagitis, pericarditis, volvulus) as well as neuromuscular and musculoskeletal complications of RFS (e.g., myelo-radiculo-plexo-neuro-myopathy, osteoporosis, osteoradionecrosis, adhesive capsulitis) are well recognized. Patients with a history of HL treated with mantle or other types of radiation are at a greatly increased risk for development of secondary cancers (including thyroid, breast, lung, and sarcoma) and accelerated cardiovascular disease (including atherosclerosis, valvular heart disease, pericardial disease, cardiomyopathy, arrhythmias, and subclavian and carotid artery stenosis) [22]. Childhood cancer survivors are at the greatest risk for complications, including radiation-induced neoplasms, osteonecrosis, and abnormal bone growth either from cranial radiation affecting the endocrine system or from abnormal maturation of growth plates affected by radiation.

Potential Treatment Complications

Medications used to treat muscle spasms as well as neuropathic and musculoskeletal pain can result in significant side effects, in some cases leading to medication discontinuation by the patient. This can frequently be avoided by slow dose titration with the goal of finding the lowest effective dose of medications. Trigger point and botulinum toxin injections carry a low risk of adverse effects if they are given by an experienced practitioner. Altered anatomy from radiation and surgery should be taken into consideration. Some of the possible side effects include pneumothorax, bleeding, and infection. Botulinum toxin injections can cause focal muscle weakness ranging from a droopy eyelid or neck extension weakness to a severe dysphagia necessitating feeding tube placement; fortunately, these effects are transient. Starting doses of botulinum toxin should be low, and only relatively strong muscles should be targeted for injections.

Definition

Repetitive strain injury (RSI) describes nonspecific upper extremity pain that often develops in occupational settings. RSIs are thought to result from the performance of repetitive and forceful hand-intensive tasks. These conditions are also referred to as cumulative trauma disorders, occupational overuse syndromes, and nonspecific work-related upper limb disorders. The varying nomenclature is controversial because it provides little insight into anatomy affected, disease severity, appropriate treatment, or expected prognosis. Classification systems of work-related musculoskeletal disorders often include specific diagnoses, such as carpal tunnel syndrome and de Quervain tenosynovitis, as

RSIs, but the consensus in recent years has been to consider RSI an entirely separate category of occupational disorder [1]. RSIs have symptom complexes that do not fit neatly into another diagnostic classification, such as specific tendinopathy or nerve entrapment. RSIs typically have few objective physical findings and little in the way of demonstrable pathologic change.

RSI is a significant medical concern; approximately 65% of reported cases of occupational illness are attributed to repeated trauma annually [2,3]. In fact, occupational musculoskeletal disorders of the hand and wrist are associated with the longest absences from work and have greater lost productivity and wages than those of other anatomic regions [2]. There is evidence that this condition is actually underreported [4]. Important risk factors appear to be repetitive motion of the arm or wrist, movements that require extremes of hand or arm position, prolonged static postures, and vibration. Other risk factors may be poor ergonomic work environment, task invariability, lack of autonomy, and high levels of psychological distress in the workplace. In addition, the female gender appears to be more susceptible to development of RSI [5]. RSIs can develop outside of the workplace in individuals who participate in hobbies or activities that expose them to repetitive motion and prolonged postures on a consistent basis. A study demonstrated that the adult acquired upper limb amputee population is at increased risk of musculoskeletal pain in the neck/upper back and residual limb as well as in the contralateral remaining arm [6].

According to the U.S. Department of Labor, Bureau of Labor Statistics, occupations that appear to be at greatest risk for RSIs are those in the service and manufacturing industries, including any job involving computer processing and keyboard use [2]. These occupations have the most demand for upper extremity intensive tasks. Because of limitations in the assessment of risk factors, quantitative levels of exposure that are “acceptable” in each occupation are not available [7]. Clinically, it appears that the onset and perpetuation of RSIs are multifactorial. There is no proven etiology of RSI, but it is thought to develop from repetitive microtrauma to muscle, tendon, nerve, loose connective tissue, or bone that exceeds the ability of the tissue to heal itself. In animal models, when chronic repetitive motion is induced, an acute inflammatory response is stimulated in the tissue. This initial response eventually

subsides and is followed by a fibrotic response that may lead to complete tissue repair if loads and repetition are sufficiently low [8]. However, in the presence of high repetition or high force, the acute inflammatory response is followed by tissue degeneration and fibrosis that leads to scarring. It is this tissue reorganization that may lead to a nonspecific pattern of pain in RSI.

Abnormal muscle fatigability may also contribute to pain [9]. Reduction in muscle blood flow and localized tissue hypoxia have been demonstrated in trapezius muscle biopsy specimens taken from assembly-line workers with prolonged, static shoulder postures who developed chronic trapezius myalgia [10]. In addition, diminished local muscle oxygenation and blood flow has been demonstrated in the forearms of individuals with RSI during static contraction, compared with controls at similar working intensities [11]. The same investigators later demonstrated that patients with RSI have an attenuated exercise-induced brachial artery blood flow and an impaired vascular endothelial function in the affected arm [12]. A subsequent study found that blood flow and oxygen consumption after exercise are similarly attenuated in both the affected and contralateral unaffected arms of patients with unilateral RSI, indicating that systemic vascular adaptations may occur [13]. These findings indicate that the underlying vasculature may be impaired in this condition. It is unclear whether these data can

be extrapolated to explain the pathophysiologic mechanism of all RSIs in the upper extremity.

There may also be a neurogenic origin for RSI. There is evidence of neural reorganization at multiple levels of the central nervous system after the performance of repetitive tasks [2]. The repeated stimulation of nociceptive afferent nerve fibers may cause the receptors to become hypersensitive, to expand their receptive fields, and to increase the excitability of secondary neurons in the spinal cord. These changes may contribute to the hyperalgesia associated with chronic pain in RSIs. Moreover, there may also be an element of central nervous system reorganization at the level of the somatosensory cortex with repetitive tasks [2]. Figure 112.1 illustrates the distribution of somatosensory pathways in the central nervous system.

Regardless of the factors that contribute to the development of RSI, there is often a complex dynamic in managing patients with work-related musculoskeletal disorders. They are often involved in compensation claims. When the injured patient takes on the additional role of claimant, the perception of both patient and caregiver can change in many aspects of the healing and rehabilitation process. It is paramount for the physician treating RSI to take the medicolegal implications into account. Indeed, the workers' compensation system has a great impact on the reporting and control of work-related disorders [14].

DRG, dorsal root ganglion. (From Nolte J. *Elsevier's Integrated Neuroscience*. St. Louis, Mosby, 2008.)

Symptoms

The predominant symptom in RSI is upper extremity pain. The discomfort often begins as a dull ache in the forearm or hand after the performance of tasks of repetitive motion. Initially, it may be intermittent and alleviated with rest. As the offending activity is repeated with regularity, the pain may increase in intensity and be triggered by minimal exertion in the workplace and even while performing simple activities of daily living, such as dressing or grooming. The symptoms usually begin in one region of the limb in a fairly localized area (e.g., wrist, elbow, or forearm) but may quickly spread to involve the entire arm and at times the contralateral arm. Pain tends to gradually increase during the workday, with peak intensity during the last hours of work. It appears to get better over the weekends and during vacations from work.

Other symptoms may include paresthesias, numbness, and weakness. If these symptoms are present, they may not follow dermatomal or peripheral nerve distributions. Patients may also complain of arm or hand muscle cramping, allodynia, stiffness, and slowing or incoordination of fine motor movements of the hand.

Patients often complain of night pain, resulting in poor sleep. A detailed investigation of sleep habits is important because sleep disruption is common in RSI. Psychological distress and depression may result if pain and sleeplessness persist. In fact, self-reported upper extremity-specific health status measured by the Disabilities of the Arm, Shoulder, and Hand (DASH) questionnaire appears to correlate with depression and pain anxiety in these patients [15]. Some patients may also exhibit maladaptive illness beliefs, such as catastrophizing and fear-avoidance.

In taking a patient's history, the clinician should attain an accurate understanding of the patient's job description and daily workstation. It is important to thoroughly evaluate the biomechanics of body position and posture as well as the physical layout of the work site. Special attention should be given to the details of specific job duties, including the frequency, duration, and conditions under which they are performed. For example, if the patient works a desk job and spends each day on a computer, it is important to inquire about desk and chair setup and placement of the computer monitor and keyboard. The clinician should also take note of the patient's perception and satisfaction with the workplace. This information can give the clinician valuable insight as dissatisfied workers are notorious for work-related medical claims.

Physical Examination

RSI is a diagnosis of exclusion. Typically, there are no objective physical findings. Hence, the physical examination should be comprehensive and focus on ruling out alternative diagnoses. It should include a thorough musculoskeletal examination with inspection, palpation, and testing of passive and active range of motion of the cervical spine, shoulder, elbow, wrist, and fingers. There is typically no evidence of muscle atrophy or other deformity. There may be pain on active and passive range of motion, but there is generally no restriction of motion when the examiner takes the joint through a full arc. There may be diffuse myofascial pain

with palpation over the symptomatic region. In addition, there may be evidence of one or more focal fibromyalgia tender points on the symptomatic as well as on the asymptomatic side [16] (Fig. 112.2).

Neurologic assessment can rule out localized nerve disease by investigating for dermatomal, myotomal, or peripheral nerve abnormalities. In RSI, deep tendon reflexes are normal and symmetric. Manual muscle strength testing should be performed but is generally inconsistent, depending on the patient's effort and pain level with exertion. Objective and reproducible strength tests can be performed with a hand or pinch dynamometer if level of strength is uncertain with examiner resistance. Computer-driven isokinetic dynamometers can also be used for more reliable measures of strength across uniaxial joints, such as the elbow. Sensory testing should be done by light touch as well as by pinprick. This portion of the neurologic examination is often difficult as subjective abnormalities are common. The reported impairments in sensation do not typically follow dermatomal distributions.

Provocative tests that reproduce specific pain patterns can help rule out alternative diagnoses. Examples include the Spurling test for cervical radiculopathy, Neer and Hawkins maneuvers for rotator cuff impingement, resisted wrist or finger extension for lateral epicondylitis, Tinel sign at the ulnar groove for ulnar neuritis, and Finkelstein test for de Quervain tenosynovitis. Provocative maneuvers that can rule out carpal tunnel syndrome include Tinel sign at the wrist, Phalen test, reverse Phalen test, and carpal tunnel compression. It is important to keep in mind that percussion over the median nerve at the wrist, the ulnar nerve at the cubital tunnel, or the radial nerve at the elbow may elicit pain or paresthesias in RSI, but this is not necessarily indicative of nerve injury.

FIGURE 112.2 Fibromyalgia of the cervical musculature. (From Waldman S. *Atlas of Common Pain Syndromes*, 3rd ed. Philadelphia, WB Saunders, 2012.)

Functional Limitations

RSI can limit upper extremity function to highly variable degrees [17]. Patients may have difficulty in performing activities of daily living at home, such as dressing, grooming, or preparing a meal. The pain impairment may prevent them from participating in recreational activities that they formerly enjoyed. They can also be quite limited in terms of their work-related activity. For example, pain may prevent a patient from being productive at work because he or she finds it difficult to use a keyboard and computer to do different tasks. Employers often advocate functional capacity evaluations to define more objectively the amount of physical labor that the patient can perform safely.

Diagnostic Studies

Diagnostic tests are ordered if the diagnosis is not clear after the history and physical examination, if the results of the testing will change management, or if the testing is needed for medicolegal reasons. The tests are used to exclude other definitive conditions that may remain in the differential diagnosis after examination. Needle electromyography and nerve conduction studies are often necessary to rule out a peripheral nerve lesion, such as median nerve entrapment at the wrist. Electrodiagnostic studies provide the distinct advantage of offering objective data by quantifying the degree of nerve impairment in a manner that is independent of the patient's pain behaviors [18]. This can be important when injured workers have interest in substantial secondary gain and may not be reliable in their effort or honesty when motor and sensory nerve function is tested on physical examination.

Imaging is likely to be normal in RSI. Plain radiographs of the suspected site of disease will generally not reveal a fracture in the absence of blunt trauma but may reveal underlying degenerative changes that may or may not account for the patient's symptoms. Magnetic resonance imaging of the cervical spine and shoulder is often ordered to rule out disc herniation, neuroforaminal stenosis, and rotator cuff disease. This study may be useful only if there is concern for one of these diagnoses on the basis of the physical examination [19]. Magnetic resonance imaging is expensive, and abnormalities such as disc bulging and degenerative spondylosis are often found in asymptomatic individuals and may not explain the current symptom complex.

Laboratory work is seldom necessary at the time of initial evaluation unless an underlying systemic illness is suspected.

Differential Diagnosis

- Cervical radiculopathy
- Myofascial pain syndrome
- Thoracic outlet syndrome
- Rotator cuff or biceps tendinopathy
- Lateral or medial epicondylitis
- Compressive neuropathies (e.g., carpal tunnel syndrome)
- de Quervain tenosynovitis
- Osteoarthritis
- Fractures

Treatment

Initial

Treatment of RSIs should focus on conservative measures. The first step is to limit exposure, if possible, to the particular repetitive activities that may have contributed to the development of the RSI and that continue to induce pain. Whenever possible, accommodations at the workplace should be optimized to allow the patient to continue to perform the duties that are required by the employer. Several strategies for computer-based occupations are discussed later in this chapter. Early return to work with transitional arrangements should be facilitated when necessary. Sick leave should be avoided because it may develop into chronic disability. A substantial proportion of workers experience additional injury-related absences even after their first return to work. Time off work has proved to be a powerful predictor of disability pension; fully following work-related restrictions can ensure that the patient remains a productive employee by going to work [20].

Unfortunately, there is little evidence for the effectiveness of any specific medical intervention for RSI. Clinical treatment is usually targeted at relief of pain and acute inflammation as well as restoration of range of motion. Inflammatory conditions are often treated with the PRICE regimen: protection (preventing further injury, perhaps by bracing), rest or activity modification (as mentioned before), ice, compression, and elevation to minimize swelling.

Icing of the limb for about 20 minutes three times daily in conjunction with wrist or elbow splinting can decrease symptoms. Other modalities that may be helpful in controlling pain symptoms in the acute phase of treatment include ultrasound, iontophoresis, and transcutaneous electrical nerve stimulation applied to the region of soft tissue pain. Manual therapy, spray and stretch techniques with a vapocoolant spray, and paraffin baths may also alleviate pain in some patients, although evidence for efficacy is lacking.

Medications may also be used to control pain and inflammation. Nonsteroidal anti-inflammatory drugs (NSAIDs) are usually the first-line pharmaceuticals for acute inflammation. There are many NSAIDs on the market from which to choose, and some can easily be purchased over-the-counter. It is often useful to try several different types of NSAIDs because patient responses can be idiosyncratic. Anticonvulsant medications, such as gabapentin, pregabalin, and carbamazepine, are also often used for pain. They are generally most effective for neuropathic pain. There is currently no evidence suggesting that they are specifically indicated in treatment of RSI. Local anesthetic patches (e.g., lidocaine) may be helpful if they are placed over a localized area of arm pain. Trigger point injections with local anesthetic or dry needling can also be considered to relieve myofascial pain. Oral narcotics are generally avoided.

Restoration of sleep can be helpful in reducing pain perception as well as in decreasing the risk for development of depression. The use of low-dose tricyclic antidepressants (e.g., nortriptyline or amitriptyline) can be effective. A randomized controlled trial found that low-dose amitriptyline did not significantly decrease arm pain

compared with placebo among participants with RSI. However, low-dose amitriptyline did significantly improve arm function and well-being [21]. In addition, the antidepressant duloxetine that is indicated for treatment of fibromyalgia pain may also be considered for treatment of pain associated with RSI. If signs of depression are present, appropriate comprehensive treatment and referral to a psychiatrist or psychologist may be indicated.

Rehabilitation

The rehabilitation of a patient with RSI is best achieved by a multidisciplinary approach with the physician overseeing the treatment plan and following the progress of the patient. A review of evidence-based management strategies suggests that biomedical treatment should not be ignored, but the psychosocial management approach appears to be more influential for occupational outcomes [22]. A referral to skilled physical and occupational therapy is essential [23]. Therapists may provide several therapeutic modalities (mentioned previously) to decrease pain and to facilitate an active stretching and strengthening program. The focus is not only on the affected limb but also on total body biomechanics and postural control at the workstation and at home. Progressive resistive exercise programs can be used, but worsening of pain symptoms with increasing exertion is often an issue. Progressive resistive exercises may have more benefit if they are introduced with small increments in resistance, allowing the patient to slowly adjust. This approach can improve participation of the patient and thus increase strength gains. Further physical conditioning with regimented aerobic training, catered to the patient's personal interests, and institution of a home exercise program may reduce pain, improve stress management, and increase work capacity. It is important to encourage physical activity as much as possible. General aerobic conditioning can be effective in encouraging a positive health perception.

Relaxation training may also be helpful for chronic, non-specific regional arm pain [24]. Continued surveillance and treatment of mental health problems can be imperative in recovery. Cognitive-behavioral therapy techniques can be used to treat the maladaptive beliefs and misconceptions that may accompany upper extremity dysfunction [25]. Moreover, weight reduction, if needed, and smoking cessation should also be included in any plan to improve overall health.

Other rehabilitative measures for RSI include the fabrication of splints and the introduction of adaptive equipment that may assist in functional activities at home and in the workplace. Some therapists are specially trained to perform work site analysis and to suggest ergonomic modifications. Modifications can range from adjustment in chair height and computer mouse position to the substitution of large-handled tools, depending on the occupation. For computer users, it is generally recommended that chair height be such that the forearms are relatively horizontal to the floor and the wrists are in a neutral position. The volar aspect of the wrist can be supported during typing by a wrist support placed on the desktop or support tray in front of the keyboard. The keyboard should be located in a position directly in front of the typist, minimizing ulnar deviation of either wrist. The mouse should be placed close to midline.

Split keyboards and those that provide a trackball can help with forearm and hand positioning. Voice-activated software is also available for those patients whose symptoms are refractory to these modifications [18]. Ergonomically designed computer touch pads, a foot-controlled mouse, and document holders are other tools that can help decrease symptoms in RSI.

There is limited evidence in published literature to confirm the usefulness of ergonomic interventions [26]. A systematic review by Goodman and colleagues [27] investigated the most effective interventions for upper extremity cumulative trauma disorders in computer users. The highest levels of evidence were found for education and training in ergonomics, forearm supports, ergonomic keyboards, ergonomic mice, and exercise and rest breaks. Most clinicians agree that such interventions are a worthwhile component of a comprehensive rehabilitation plan. Ergonomic interventions *may* make the workplace more comfortable, encouraging the patient to return to work and possibly preventing work disability [28]. Education about proper ergonomics should empower patients to make low-cost changes on their own at work and at home.

Many factors can limit the effectiveness of work hardening and work conditioning programs. Individuals who are having difficulty in returning to their previous level of work activity should be evaluated for alternative jobs. This can involve consideration of a new position with the current employer, if it is mutually agreed on. Job redesign that enriches career development opportunities may be effective. In fact, studies suggest that interventions aimed at altering workers' perceptions of monotonous or tedious work, through better job development opportunities, an increase of latitude over working patterns, and the improvement of communication between employers and employees, may be beneficial and cost-effective to the employer [29-31]. However, in some instances, an entirely different vocation must be pursued. If this is the case, a consultation with a vocational rehabilitation specialist is advised.

Procedures

Procedures are rarely indicated in RSI. In a population of patients with such a nondefinitive diagnosis, treatment failures are frequent. Therefore, trigger point injections, lateral epicondylar injections, carpal tunnel injections, and the like can be attempted to see if symptoms improve. The risk and benefits of each procedure should be explained in detail, including the risk of no relief of pain.

Surgery

Surgery is not indicated for RSI.

Potential Disease Complications

The most feared complication of RSI is increasing functional impairment and disability in all aspects of life. Negative outcomes can occur if the patient feels incapable of using his or her arms and hands. This may result in the inability to participate in home, work, and recreational activities. Depression and social isolation may accompany prolonged periods of absence from work.

Potential Treatment Complications

Treatment complications are rare. Most complications are associated with pain medication side effects. Analgesics and NSAIDs have well-known adverse reactions that most commonly affect the gastric, hepatic, and renal systems. Anticonvulsants can cause fatigue, ataxia, edema, or nausea. Tricyclic antidepressants have a high profile of fatigue, dizziness, dry mouth, and constipation. Patients should be informed of the side effect profile of each medication before administration. The patient's complete medication list should be reviewed to address potential adverse reactions between medications taken concurrently.

524.60 Unspecified temporomandibular joint disorder

ICD-10 Codes

M26.60 Temporomandibular joint disorder, unspecified

M26.29 Other specified disorders of temporomandibular joint

Definition

The temporomandibular joint (TMJ) is the synovial articulation between the mandible and the cranium. The TMJ is unusual in that the articular surfaces are covered by fibrous tissue rather than hyaline cartilage, as in most joints, and that it is divided into two joint spaces by an intra-articular disc. TMJ dysfunction (TMD) includes a collection of symptoms that refer to intrinsic and extrinsic TMJ conditions. These conditions are commonly referred to as TMJ, although they should more accurately be referred to as TMD to specify a difference between the joint itself and a true dysfunction. These symptoms include issues that cause

pain or dysfunction relating to the TMJ itself as well as to the muscles of mastication. Because of the high number of issues that can be manifested in the facial and temporal area, a thorough history and physical examination are necessary to identify the true cause of pain in this area.

Studies report that approximately 28% of the population exhibits signs of TMD. Of those people suffering from symptoms, 14% had actual restricted range of motion of the mandible [1]. There is historically a predominance in women (5:1 versus men), and it occurs most often in patients between the ages of 15 and 45 years [2–4]. The most common cause of TMD is myofascial pain dysfunction of the muscles of mastication, and stress is often associated with this dysfunction [5–7]. This dysfunction can also be associated with macrotrauma, such as a motor vehicle accident, or microtrauma, such as teeth grinding and clenching at night. Identification of specific mechanical causes is important as well to correct issues that may be lending themselves to TMD. Examples of mechanical causes can be prolonged mouth or upper respiratory breathing, postural abnormalities, and sleeping prone with increased pressure on the TMJ. A third major cause of TMD is dental malalignment. No matter the physical cause, stress and psychosocial impact should always be considerations [5–7].

Within the TMJ, there is a biconcave cartilage disc that normally moves with the mandibular condyle in the fossa (Fig. 113.1). The TMJ is a modified hinge joint that has two separate periods and types of motion. In the initial third of opening, the joint moves in a rotational manner. In the latter two thirds of opening, the joint moves in both a rotational and translational motion, allowing increased range of motion. Muscles commonly involved with TMD are the temporalis, masseter, and internal and external pterygoids. The TMJ is innervated by branches of the mandibular nerve. Irritation to these nerves, muscle spasms, intra-articular disease, and myofascial irritation can cause symptoms related to TMD [8].

FIGURE 113.1 Anatomy of the temporomandibular joint. (Image from <http://www.usa.gov/Topics/Graphics.shtml>.)

Symptoms

Symptoms of TMD are varied and may at first seem unrelated. A common complaint with which patients may present is noise stemming from the TMJ, including crepitus, clicking, grinding, and popping. Pain at the level of the TMJ or surrounding areas also is a common complaint that may lead a patient to seek care from a health care provider. Whereas pain directly over the TMJ or mandible may lead patients to believe that they have a problem with the jaw, TMD can often be manifested as nontraditional headaches or upper cervical pain as well and is often made worse with chewing. Another common complaint in TMD is decreased range of motion of the jaw with “locking” of the joint in severe cases. Other symptoms, such as generalized facial pain, earaches, tinnitus, dysphagia, and even photosensitivity, have been reported with TMD [7,9].

Physical Examination

The diagnosis of TMD is made by observation of the range of motion of the mandible and palpation of the musculoskeletal structures of the face and head. It is essential to determine whether the patient has an intrinsic or extrinsic dysfunction of the TMJ. The translation can be felt by placing a finger over the TMJ just anterior to the tragus of the ear and asking the patient to open the mouth wide and repeat this motion. With palpation, the provider should identify whether the movement is smooth or if crepitus or joint dysfunction is noted. At maximal mouth opening, measure the opening in millimeters between the upper and lower incisal edges; the normal range is between 38 and 45 mm

FIGURE 113.2 Magnetic resonance image of normal temporomandibular joint in closed position. The intra-articular disc is marked by the arrow. (Image from <http://www.usa.gov/Topics/Graphics.shtml>.)

[10,11]. The average individual should have roughly three fingerbreadths between the teeth without any discomfort or pain. Monitoring of mandible opening for lateralization during opening can also suggest pathologic change. Have the patient also move the mandible left and right, noting restriction on one side versus the other or pain with this motion.

If the disc in the TMJ is displaced (Fig. 113.2) or if there are arthritic changes, clicking and crepitus can be heard or palpated as the disc clicks into its normal position with jaw opening. There will also be a click as the disc slips out of its normal position on closing. If the disc is fully displaced (anterior disc displacement with no reduction), there is no clicking and limited opening with an opening shift toward the locked side and no lateral movement toward the contralateral side. Full lateral and protrusive movements with limited openings might suggest muscle spasm versus disc displacement.

The provider gently palpates both masseters and temporalis muscles, insertion of the sternocleidomastoid muscle, and suboccipital area; any sensitivity should be noted. If the TMD symptoms are of new onset after trauma, a thorough cervical spine examination should be completed as well.

Functional Limitations

Pain may limit speaking and mastication. In patients with chronic pain, sleep and mood disorders may persist as well. Underlying psychosocial stress or depression that may be leading to TMD must also be identified as a possible hindrance of function [6].

Diagnostic Studies

Radiography can identify major arthritic changes, malalignments, or fractures but is not diagnostic if there are no abnormal findings. If it is available, panoramic oral radiography

FIGURE 113.3 Medial displacement of the temporomandibular joint disc (arrow). (Image from <http://www.usa.gov/Topics/Graphics.shtml>.)

may be beneficial to visualize bilateral TMJs and alignment. Magnetic resonance imaging is necessary to visualize the disc and to provide definitive diagnosis of the disc position (Fig. 113.3), but it is not generally required for nonlocking joints that click [5,8].

Differential Diagnosis

- Trauma to surrounding structures
- Fractures
- Tumors
- Infected teeth or gums
- Acute trismus or muscle spasm
- Facial nerve injuries
- Upper cervical whiplash injuries
- Headaches
- Parotid gland disease
- Trigeminal neuralgia

Treatment

Initial

There are different philosophical approaches of dental clinicians managing TMD. Some dentists attempt to calm symptoms with oral appliances and have the patient discontinue the daytime appliance after the first few months. Others believe that permanent bite changes are necessary for long-term relief and will grind the bite surfaces of teeth to balance the irregular bite. If there is dental malalignment, an occlusal stabilizing appliance may prove beneficial.

Acute pain with full lateral mandibular excursive and protrusive movement is treated as an acute muscle spasm. Nonsteroidal anti-inflammatory medications, moist heat, and ice massage as well as eating of softer food during the acute period may decrease pain and ease

the burden on the musculature [10]. If the pain does become chronic in nature, lasting more than 3 months, more attention should be paid to stress as a common cause, and medications that treat both pain and emotional stress, such as tricyclic antidepressants, should be considered [7].

Rehabilitation

Manual manipulation can be beneficial in treatment of TMD when the underlying dysfunction is myofascial or muscle spasm. For a unilateral muscle spasm causing TMD, the muscle energy technique takes the patient's mandible away from the restriction and into the barrier away from the direction of chin deviation, and the patient pushes back three times. After the third activation is completed by the patient, the provider should take the jaw laterally to the physiologic barrier. If a patient has bilateral muscle spasms, have the patient open the mouth against resistance and close the mouth against resistance, repeating each three times to attempt to release the TMJ complex. For more complex TMD cases in which there is some locking, an intraoral technique may be used. In this technique, the provider should put on gloves (with cotton or gauze wrapped around the thumbs). Start by placing the thumbs on the patient's lower molars and wrap the remaining fingers around the ramus of the mandible, pushing inferiorly and anteriorly until release is felt. This technique stretches bilateral muscle groups at the same time as well as allows myofascial release [11].

Jaw exercises and stretching of the muscles of mastication are paramount to treatment of acute TMD as well as to prevention of progression or recurrences. Following Rocabado's original research, main goals should focus on joint distraction, elimination of compression, restoration of physiologic articular rest, mobilization of soft tissues, and improvement in the condyle-disc-glenoid fossa relationship. A working example of this exercise is the placement of hands under the chin and opening downward with pressure against the hand for a few seconds at a time for six times, six times a day (classic six by six exercises), which may benefit the patient [12].

Stress reduction and biofeedback to decrease teeth grinding or clenching can be beneficial to help break acute spasms and to avoid progressive weakness or dysfunction.

Correction of posture also may be beneficial to patients suffering from TMD. Holding a posture with increased thoracic kyphosis and decreased cervical lordosis (forward leaning) can increase stress on the TMJ as well as lead to myofascial dysfunction. Other postural issues, such as postures or chronic dysfunction of the subcranial spine, most notably the occipitoatlantal joint, can contribute to TMJ pain. Correction of this posture with exercise and active therapy, such as chin tucks and scapular retraction, is recommended. Also, for patients who tend to sit in this head forward position, a lumbar roll or support while sitting may also be beneficial.

Along with the multiple modalities discussed, the patient should be counseled on avoidance of specific tasks that may exacerbate the symptoms or stress the jaw, such as yawning, singing, chewing gum, or resting the chin on a hard surface.

Procedures

For patients diagnosed with a myofascial cause of TMD, trigger point injections are a viable option to aid in release of the taut bands within these muscles. For recurrent myofascial cases, trigger point injections should be considered an adjunct to continuing therapy to correct the mechanical issues leading to repeated episodes. Intra-articular injections may be beneficial for patients with TMD that has not responded to more conservative treatments. Multiple injectants have been used in TMJ dysfunctions, including local anesthetic, steroids, and viscosupplementation [8,13]. Botulinum toxin has also demonstrated some efficacy in refractory cases and may be considered before surgical intervention [14].

Complementary medicine techniques can also be considered in approaching the treatment of a patient with TMD. For example, Chinese scalp acupuncture can play a role in management. This technique addresses the sensory area of the scalp for abnormal sensations of the face that are hypersensitive, including pain, tingling, and numbness. Treatment by scalp acupuncture has shown positive results in disorders with TMJ pain. Treatment of the lower two fifths of the sensory area focuses on the face, head, and TMJ pain, and it has proved to be a useful adjunct to current treatments [15].

Surgery

Although surgery is rarely needed, there are surgical procedures that may benefit patients with refractory TMD. If imaging demonstrates intra-articular bone or disc fragments, surgical removal is an option. For patients with refractory TMD not responding to less invasive treatment, shaving of the condyle has also been shown to be beneficial. A joint replacement is possible for the TMJ, allowing return to function (Fig. 113.4). This is more often used when there is significant ankylosis of the joint, which may be seen in patients with severe cases or with a neurogenic cause due to paralysis of the muscles of mastication.

Total joint replacement

FIGURE 113.4 Temporomandibular joint replacement. (Image from <http://www.usa.gov/Topics/Graphics.shtml>.)

If the problem persists for several weeks or remains refractory to initial treatments and therapies, referral to a provider specializing in TMD may be warranted. When there is unilateral restricted translation of the TMJ and limited opening with a deviation or acute inability to close the mouth, called an open lock or subluxation, consultation with a TMD specialist with experience in unlocking these subluxations is recommended.

Potential Disease Complications

A potential complication is bruxism or rhythmic grinding of the teeth from other conditions, such as traumatic brain injury, especially at night. Trismus, or overactivity of the muscles of mastication, can restrict jaw mobility and be a severe functional problem. If there is anterior disc displacement without reduction, it can limit mouth opening on that side and cause significant pain if there is forced opening. Degenerative joint disease in the older population can affect the TMJ with increased symptoms of pain, tenderness, crepitus, and limitations of jaw movement. TMJ ankylosis may occur from rheumatoid arthritis or trauma, and surgery is often needed. Infections of the TMJ are rare, and there are usually local or systemic signs of inflammation. Finally, local TMD pain during several months can become a widespread chronic pain disorder affecting sleep and causing mood swings, depression, and anxiety.

Potential Treatment Complications

Oral appliances used 24 hours a day for many months may create a permanent bite change. When this occurs, the patient cannot bring his or her teeth fully together when clenching. If it is not properly managed, this may increase symptoms. Athletic mouth guards bought in stores and heated to conform to bite may aggravate TMD symptoms. Inherent risks in injection techniques include ecchymosis, bleeding, infection, and vascular or nerve damage. Medications used to treat TMD carry the same risk as they would for treatment of any pain condition as defined by each individual medication. Surgical interventions have risks similar to those of any open surgical procedure, and these should be discussed between the surgeon and the patient.

G89.0 Central pain syndrome

Definition

Central post-stroke pain (CPSP), formerly known as thalamic pain syndrome, is a chronic complex disabling pain syndrome characterized by pain and temperature sensation abnormalities after a cerebrovascular accident, infarct, or hemorrhage. It was first described, with pathophysiologic correlation to a lesion in the thalamus, in 1906 by Dejerine and Roussy as a “severe persistent, paroxysmal, often intolerant pain on the hemiplegic side, not yielding to analgesic treatment” [1]. There were previous descriptions of pain after a central lesion by Edinger [2] and others earlier in the 19th century.

The disease affects up to 8% of patients with stroke and, in one study, 9% of hemorrhagic stroke patients with thalamic lesions [3–5]. Pain onset in stroke patients occurs weeks to months after a cerebrovascular accident [5]. CPSP is considered a persistent central neuropathic pain that follows an ischemic or hemorrhagic stroke without a peripheral cause. Although the pathogenesis remains unclear, there appears to be involvement not only of the thalamus

as initially studied by Dejerine but of the spinothalamic pathway because of the pain and temperature sensitivity [6,7]. Interestingly, not all patients with lesions along the spinothalamic pathway have CPSP [8,9]. Many CPSP patients have many lesions noted on magnetic resonance imaging that are unrelated to the pain [10].

Predictors as to those at risk are unclear, but in one study controls with thalamic stroke without thalamic pain had lesions mainly in the more anterolateral nuclei. Thalamic pain patients were noted to have lesions mainly in lateral and posterior thalamic nuclei on magnetic resonance imaging [11]. In one study at 16 months, patients with higher pain intensity were female [12].

Symptoms

CPSP is characterized by mild hemiplegia, hemihypoesthesia, hyperpathia with burning sensation, hemiataxia, astereognosis, dyskinesias (especially choreoathetosis), and positive or negative pain sensations that occur for hours to continuously in the entire half the body, arm, leg, foot, or hand [13,14]. Patients describe pain sensations as burning, cold, stabbing, sharp, aching, pricking, squeezing, shooting, tingling, or heavy when they are exposed to changes in temperature measured by a thermal probe, monofilament for tactile stimuli, and brushing with a stiff brush typically used for oil painting [15]. Particularly excruciating are the sensory abnormalities, especially the thermal sensations that can include burning, scalding, or burning and freezing in addition to other vague descriptions of positive and negative sensory abnormalities. Symptoms can be constant or intermittent, described as burning by some CPSP patients, and triggered by touching of an item, being touched, or changes in temperature [14]. Because of the variable onset and symptom constellation, patients are often misdiagnosed [16].

Physical Examination

It is important in considering the diagnosis of CPSP to perform a thorough musculoskeletal and neurologic physical examination to rule out other causes of pain. Physical findings in patients with CPSP may include mild or more

severe hemiplegia, hyperesthesia, or hypoaesthesia. Patients may have impaired pinprick, temperature, and touch sensation, whereas vibration and joint proprioception are less commonly affected [10].

In a prospective study of 207 stroke patients, 87 subjects (16 with CPSP and 71 with no pain) with abnormal sensation were observed. The CPSP group was noted to have more abnormal sensibility to cold and warm stimuli compared with nonpain subjects with abnormal sensation. The 16 CPSP patients had evoked dysesthesia or allodynia (sensation of pain by stimuli that are usually nonpainful) [5].

Functional Limitations

Strokes that cause CPSP are typically associated with only mild hemiplegia, though some patients can have moderate or severe hemiplegia and the functional limitations that accompany these. The pain of CPSP can often be a much more severe cause of functional limitation, at times to the point of being incapacitating.

Diagnostic Studies

Brain imaging of patients with CPSP will typically show a lesion in the spinothalamic pathway, but not all patients with such lesions will have CPSP [8,9].

Differential Diagnosis

Peripheral neuropathy
Traumatic brain injury
Syringomyelia
Multiple sclerosis
Complex regional pain syndrome
Shoulder disease (frozen shoulder, rotator cuff disease)
Deep venous thrombosis

Treatment

Initial

Historically, CPSP has been resistant to both medical and surgical management. Despite the severe impact on quality of life for patients with CPSP, there is limited scientific evidence of its treatment [17].

The only medications that have shown pain reduction in a randomized controlled trial are amitriptyline (at least 75 mg daily) [18], lamotrigine (at least 200 mg daily) [19], and gabapentin [20]. Thus, these medicines are considered first-line management for CPSP. Unfortunately, even with these medicines, only mild pain relief was achieved, and many patients did not respond at all. Other medicines that have been found to have some benefit in open trials, such as nortriptyline, desipramine, imipramine, doxepin, venlafaxine, maprotiline, gabapentin, pregabalin, carbamazepine, mexiletine, fluvoxamine, and phenytoin, are considered second-line treatment [10,17–19,21–28].

For patients resistant to treatment, opioids (such as levorphanol, studied in a double-blind randomized controlled study) have been used, resulting in some pain reduction in a small group but not in a large population [29]. In one

study, intravenous morphine showed a modest short-term benefit in some patients [30]. Long-term benzodiazepines are not recommended because of potentiation of inhibitory effects of γ -aminobutyric acid, but there is a possible role of short-term use in CPSP patients with anxiety [13]. Intravenous administration of the γ -aminobutyric acid agonist thiopental, intravenous propofol, and intrathecal baclofen alleviated some pain in patients with CPSP [31–33], but oral doses of baclofen and amobarbital were ineffective [33,34].

Rehabilitation

Rehabilitation begins with management of the various deficits resulting from the stroke. Barriers to treatment include cognitive and communication limitations due to the cerebrovascular event [16].

To date, CPSP has been difficult to treat with medical or surgical interventions [16]. The pain in CPSP is a “false” signal being generated by the brain. Pain can be a useful symptom indicating an injury, but in CPSP there is no corporeal injury. It would be ideal if some method could be found to “connect to” and retrain the thalamus or other brain areas to the fact that there is no injury, so there should be no pain. For movement problems after stroke, mirror therapy [35], in which visual feedback from the reflection of the good limb helps regularize the motor control loop, can be beneficial [36]. This approach does not work for CPSP (even in patients with CPSP and hemiparesis after stroke for whom mirror therapy helped the hemiparesis), nor should one expect it to because the problem is sensory pain, not a movement difficulty.

Procedures

There has been one case report finding acupuncture helpful in CPSP [37]. Acupuncture, perhaps by sensory stimulation, may be a way to “reconnect” with and retrain the thalamus or associated structures. Further studies of acupuncture for CPSP are warranted.

Surgery

When all other modalities have failed, deep brain stimulation has been tried in a couple of cases. For example, one male patient had some improvement in pain at 6-month follow-up [38]; another male patient with deep brain stimulation by an electrode implanted in his periventricular gray region had pain relief lasting 4 months [39].

Neurosurgical destructive options include medial thalamotomy and mesencephalic tractotomy, which in limited cases of patients with central and deafferentation pain improved the allodynia and hyperpathia, but with less promising outcome for the burning or dysesthetic pain [40]. As ablation is considered the final resort, more conservative measures, including deep brain stimulation, should be tried.

Potential Disease Complications

Disease complications include severe pain and its typical sequelae that affect the quality of life of the individual with CPSP. Because of the physical and psychological effects of central pain, work and social life are often affected,

requiring different cognitive and behavioral techniques to cope [41]. In one study, 27 patients with CPSP reported pain to be a great burden, and most rated the intensity as high, interfering more with leisure activities compared with brainstem lesions [42]. Problem-centered coping with focus on external or environmental etiology is used more often by men, whereas emotion-centered coping is more often used by women. For example, women in one group were noted to use spiritual and religious activities as coping strategies more often than men did [41].

Potential Treatment Complications

Treatment complications include adverse effects of the medications or surgical procedure and vary by the medication or surgery implemented. It is important to consider and to minimize drug interactions in patients, especially those who are taking multiple medications as these patients often are.

Thoracic Outlet Syndrome

Karl-August Lindgren, MD, PhD

Synonyms

Cervical rib syndrome
Costoclavicular syndrome
Scalenus anticus syndrome

ICD-9 Code

353.0 Thoracic outlet syndrome

ICD-10 Code

G54.0 Thoracic outlet syndrome

Definition

Thoracic outlet syndrome is a symptom complex caused by compression or irritation of the neurovascular structures as they leave the thoracic cage through its narrow outlet. The thoracic outlet contains many structures in a confined space. The base of the thoracic outlet is formed by the first rib and the fascia of Sibson, which is attached to the transverse process of the seventh cervical vertebra, the pleura, and the first rib. The outlet is bounded superiorly by the subclavius muscle and the clavicle, anteriorly by the anterior scalene muscle, and posteriorly by the middle scalene muscle. The brachial plexus and the subclavian artery pass over the first rib between the anterior and middle scalene muscles (Fig. 115.1).

Neurovascular compression occurs most frequently at three levels:

- in the superior thoracic outlet, bordered posteriorly by the spine, anteriorly by the manubrium, and laterally by the first rib;
- in the costoclavicular hiatus, bordered anteriorly by the anterior scalene muscle, posteriorly by the middle scalene muscle, and caudally by the first rib; and
- in the costoclavicular passage, bordered laterally by the clavicle, posteriorly by the scapula, and medially by the first rib.

The clinical symptoms of thoracic outlet syndrome are divided into categories according to the structures under pressure. True neurologic thoracic outlet syndrome is often caused by the distal C8-T1 roots or proximal fibers of the lower trunk of the plexus being stretched over a taut congenital band extending from the tip of a rudimentary cervical rib to the first rib. The most common form of thoracic outlet syndrome is the disputed neurologic thoracic outlet syndrome. The term *disputed* has been chosen because so many of the basic tenets of this syndrome are in dispute. Symptoms caused by pure venous compression (venous thoracic outlet syndrome) occur in 1.5% of patients and are manifested as axillary-subclavian vein thrombosis, usually in young patients engaged in vigorous physical activity that emphasizes upper limb and shoulder motion (such as cricket, tennis, and baseball). Arterial thoracic outlet syndrome is very rare and may be suspected if the patient presents with claudication of the arm, coldness, and ischemia of a finger or a hand. Individuals who have congenital bone or fibromuscular variations at these spaces and experience trauma are at risk for development of thoracic outlet syndrome. Anatomic variations and anomalies probably play a secondary role in the etiology. Congenital bands and ligaments are observed in a large majority of patients with thoracic outlet syndrome, and nine different types have been recognized [1]. In a human cadaver study, only 10% had a bilaterally normal anatomy. Anatomic anomalies of the thoracic-cervical-axillary region were found in 60% of human fetuses [2]. It is suggested that anatomic abnormalities confer a predisposition to symptoms of thoracic outlet syndrome after stress or injury [3]. Variation in the course of the brachial plexus that may predispose to symptoms of thoracic outlet syndrome has also been presented. Cervical ribs are regarded as predisposing factors, and a prevalence of cervical ribs was found to be 2.21% in a London population [4]. However, cervical ribs are present since birth. In 80% of patients with cervical ribs, symptoms did not develop until after a neck injury. Post-traumatic thoracic outlet syndrome has been presented in several articles [5–7].

According to Roos [1], anomalies are always the reason behind symptoms of thoracic outlet syndrome. However, only a few other surgeons have observed such anomalies. In the case of the first rib, the costovertebral and costotransverse joints allow a fair amount of rotation to take place along the long axis of the rib. Moreover, this rib has attached to it the anterior and middle scalene muscles, which act either

FIGURE 115.1 Anatomy of the thoracic outlet area. (Reprinted from the Christine M. Kleinert Institute for Hand and Microsurgery, Inc.)

by raising the thorax or by flexing and rotating the cervical part of the spine. In consequence, this first rib bears more stresses and strains than any of the other ribs, and these are greatest at the costotransverse joint [8]. Osteoarthritic changes are found more frequently in the costotransverse joint of the first rib. The lack of a superior supporting ligament may explain why this joint of the first rib is relatively weaker than those of the other ribs [8].

The elevation of the ribs during inspiration increases the anteroposterior diameter of the upper thorax. The range of this motion is reduced in older people. A disturbance of the function of the upper thoracic aperture will predispose to thoracic outlet syndrome symptoms. A dysfunction of the first rib at the costotransverse joint causes a restricted movement of the first rib [9]. In patients with thoracic outlet syndrome, the C8 and T1 nerve roots are most commonly affected. These roots constitute the part of the brachial plexus closest to the costotransverse joint. The stellate ganglion is located in the immediate vicinity of the first costotransverse joint and has numerous connections to the C8 and T1 roots. Minimal trauma associated with static, repetitive work, especially in young women, can cause abnormal stress on the upper aperture, and the poorly stabilized first rib can subluxate at the costotransverse joint. A subluxation at the first costotransverse joint could irritate

FIGURE 115.2 The hands of a patient with true neurologic thoracic outlet syndrome. Wasting of the muscles is clearly shown in the left hand.

the nerve roots C8 and T1 emerging in front of this joint. This irritation could explain the predominantly subjective pain and sensory loss in the ulnar distribution. The weakness of the hand and the various symptoms resembling complex regional pain syndrome may be explained by the irritation of the stellate ganglion.

Symptoms

True neurologic thoracic outlet syndrome is manifested with a long history of sensory symptoms, mainly along the medial forearm, associated with hand weakness and wasting, particularly of the thenar muscles (Fig. 115.2). In the upper plexus type presented by Roos [1], pain is felt over the brachial plexus radiating from the ear, through the anterior cervical region, over the clavicle into the upper part of the chest, posteriorly into the rhomboid and scapular areas, across the trapezius, and down the outer arm into the radial aspect of the forearm in a C5-C6 distribution. In the lower plexus type, pain is felt in the supraclavicular and infraclavicular fossae, radiating into the upper part of the back and from the axilla down the inner arm along the ulnar nerve distribution.

In contrast, disputed neurologic thoracic outlet syndrome possesses none of these characteristics. The most common symptoms are pain and paresthesias in an ulnar distribution and numbness, tingling, weakness, or dysfunction of the hand. The list of symptoms attributed to disputed neurologic thoracic outlet syndrome is long. These patients are often told by their physicians that their symptoms are exaggerated or that their complaints are not real. Coldness, easy fatigability, ischemia of a finger or a hand, and pallor on elevation are considered to be symptoms of arterial origin. Swelling, discoloration, and a heavy feeling in the hand are considered to be symptoms of venous origin. Swelling, hyperesthesia, discoloration, and a feeling of alternate cold and warm could also be signs of complex regional pain syndrome. Traction on the stellate ganglion has also been considered a possible cause of pain in these patients [8]. In general, in the absence of peripheral emboli, most “vascular symptoms” or “Raynaud phenomena” probably

result from irritation of the sympathetic nerves rather than from compression of the subclavian artery in the thoracic outlet. A common feature of the symptoms is their intermittence and provocation by use of the arm above shoulder level. Aggravation of the symptoms often occurs after rather than during exercise.

Physical Examination

The diagnosis of thoracic outlet syndrome is a clinical one based on a detailed history and physical examination. This takes time and effort. Years of inappropriate diagnosis and ineffective therapy take a heavy toll on these patients. In the physical examination, the individual as a whole must be taken into consideration. One must remember that many of these patients have some psychological complaints. A thorough clinical examination including a logical explanation for the symptoms will often relieve the psychic burden.

The physical examination starts with an inspection of the neck, shoulders, and upper extremities. Color, muscle atrophy, edema, temperature, and nails are examined. This examination requires the patient to be examined with the shirt off. The cervical spine is then examined to exclude symptoms of cervical origin caused by a cervical disc or spondylarthrotic intervertebral foramen. A typical pain radicular in C5 to C8 distribution indicates that a nerve root irritation is present. A local distribution of pain with neck extension indicates a facet joint problem.

A neurologic examination is performed to include sensory testing, muscle strength testing (C5-C8), and reflexes. Tinel sign is tested to exclude carpal tunnel syndrome. Palpation of the median, ulnar, and radial nerves from the axilla to the hand may reveal tenderness. This tenderness will vanish if a successful therapy is administered [10].

Almost all clinical tests used in the examination of the patient with thoracic outlet syndrome aim to provoke the symptoms felt by the patient, presuming that the compressing structure may be provoked to irritate the neurovascular bundle in the area of the thoracic outlet during the test. These maneuvers are unreliable in general [11]. A clinical test in extensive use is the Adson test [12]. With the patient sitting, hands resting on the thighs, both radial pulses are simultaneously palpated. During forced inspiration, hyperextension of the neck, and turning of the head to the affected side, the radial pulse is palpated for obliteration, and auscultation is done for supraclavicular bruit. The test has changed during the years. In 1927, when Adson described his test, the vascular changes were considered to be pathognomonic of thoracic outlet syndrome. Later, neurologic changes occurred more frequently than vascular ones, and these can be detected better when the head is rotated to the contralateral rather than the ipsilateral side, as initially described.

Radial pulse obliteration or subclavian bruit is found in 69% of normal patients [13]. All studies clearly indicate that pulse obliteration with the arm and head in various positions is a normal finding and has no relation to thoracic outlet syndrome.

In the hyperabduction test, symptoms are reproduced by hyperabduction of the arm. However, more than 80% of normal individuals experience obliteration of the radial pulse during this test [14]. In the exaggerated military maneuver, also called Eden test, symptoms are reproduced by

pulling back the acromioclavicular joint in an exaggerated military "attention" position. The neurovascular structures could be compressed between the first rib and the clavicle, without any anatomic predisposing factors. This maneuver is also referred to as the costoclavicular test. Arterial compression is found in 60% of asymptomatic individuals by this test.

In the abduction-external rotation test, also called Roos test or elevated arm stress test (EAST), the hands are in the "stick up" position and are then repeatedly opened and closed for 3 minutes. Roos [1] considered the symptoms to be due to both arterial and brachial plexus compression and referred to this procedure as a claudication test; he was later convinced that thoracic outlet syndrome was neurologic rather than vascular in origin but claimed that the EAST procedure was the most reliable procedure. Roos has also claimed that the EAST procedure has great specificity, with a positive result in thoracic outlet syndrome but generally negative results in carpal tunnel syndrome and cervical radiculopathy. However, in a controlled study, it was found that the EAST procedure is an excellent test for carpal tunnel syndrome; the result is positive in 92% of patients with carpal tunnel syndrome and in 74% of normal controls [15]. Positional compression during all of these tests is a common phenomenon in normal subjects, and diminishing of the pulse in Adson test, the costoclavicular maneuver, and the hyperabduction test is considered to be a normal finding rather than a pathologic one. None of these tests unequivocally establishes the presence or absence of thoracic outlet syndrome. Ribbe and colleagues [16] used a "thoracic outlet syndrome index" to establish the diagnosis of thoracic outlet syndrome. According to these authors, a patient with thoracic outlet syndrome should have at least three of the following four symptoms or signs:

1. A history of aggravation of symptoms with the arm in the elevated position
2. A history of paresthesia in the segments C8-T1
3. Tenderness over the brachial plexus supraclavicularly
4. A positive "hands-up" (abduction-external rotation) test result

Because all of these provocative maneuvers are unreliable, one should examine the function of the thoracic upper aperture. The function of the upper thoracic aperture should be analyzed with the cervical rotation-lateral flexion test [17]. The test is carried out as follows. The neutrally positioned cervical spine is first passively and maximally rotated away from the side being examined and then, in this position, gently flexed as far as possible, moving the ear toward the chest. This is done in both directions. A restriction blocking the lateral flexion part of the movement indicates a positive test result; a free movement indicates a negative test result (Fig. 115.3). This test indicates an abnormal function of the upper thoracic aperture. The test is indicative of a subluxation of the first rib at the costotransverse joint. The test has been used to identify patients who did not gain from surgery [18] as well as in a 2-year follow-up study after conservative treatment [10].

In the surgery series [18], it was hypothesized that the remaining stump of the first rib was subluxated and that is why the symptoms persisted after surgery. The importance of the length of the remaining stump has also been stressed

FIGURE 115.3 The performance of the cervical rotation-lateral flexion test. **A**, The head is rotated away from the side to be examined. **B**, In this position, the neck is tilted forward, bringing the ear toward the chest. If this movement is restricted, the test result is considered positive and is indicative of a malfunction of the first rib. A normal free movement indicates a negative test result. (Reproduced with permission of Kustannus Oy Duodecim.)

by other authors [19,20]. It is mandatory to analyze the function of the upper thoracic aperture and not rely only on provocative maneuvers that may lead to unnecessary surgical interventions.

Functional Limitations

The patients with symptoms of thoracic outlet syndrome have difficulty in working over the horizontal level, such as cleaning windows and putting up draperies. Static work, such as working with a keyboard, may be difficult because of paresthesias and difficulty in controlling the movements of the arm. Many patients cannot “rely” on the hand. Sleep is disturbed because of pain and tingling after exertion during the day.

Diagnostic Studies

Radiologic examination in the thoracic outlet syndrome can detect cervical ribs, bone anomalies of the first or second ribs, tumors, or the “droopy shoulder” syndrome. The incidence of arterial compression of clinical significance is extremely low, and arteriography should not be used in the diagnosis of thoracic outlet syndrome, except in patients with signs of pronounced compression or ischemia. Arterial compression inside the thoracic outlet can be detected with Doppler ultrasonography.

Magnetic resonance imaging has been used to detect anomalies, but these may not correlate with symptoms [21]. Functional magnetic resonance imaging may show a smaller distance between the first rib and the clavicle, but the significance remains to be shown. A cineradiographic study can detect abnormal movement of the structures of the upper aperture, but this can be detected with clinical tests [17].

Somatosensory evoked potentials can document the neurocompressive component of thoracic outlet syndrome and provide an objective assessment. The theory of the “double

crush” syndrome suggests that nerve compression at one level makes the whole nerve more vulnerable to compression injury at another level. Symptoms after an unsuccessful carpal tunnel operation disappeared after a first rib excision [22]. The double crush phenomenon should be taken into account and neurophysiologic examination should be performed to exclude more distal sites of nerve compression than the thoracic outlet, such as nerve entrapment in the carpal tunnel.

Differential Diagnosis

- Radiculopathy
- Multiple sclerosis
- Syringomyelia
- Glenohumeral instability
- Tumors of the cervical spine
- Pancoast tumor
- Myofascial pain syndrome in the cervical region
- Trapezius strain

Treatment

Initial

After the thorough clinical examination and detailed history (including the question, “Have you had a trauma to your neck region?”) [5,6,23], what the examining physician suspects to be the origin of the symptoms must be explained to the patient. Good pain management, not only using pain medications but also taking into account sleeping hygiene, is important. A multiprofessional team [24] should be consulted so that all therapy modalities are taken into account. This includes physiatrists, physiotherapists, occupational therapists, social workers, and psychologists; also, there must be a possibility to consult specialists in neurology and psychiatry, thoracic surgeons, and neurosurgeons.

Rehabilitation

The outcome of conservative therapy varies among different studies. Sällström and Celegin's program [25] brought relief to 83% of patients with mild symptoms but only 9% of those with severe symptoms. Even a success rate of 100% has been reported (a supervised physiotherapy program of graduated resisted shoulder elevation exercises in eight patients). Almost all authors have emphasized exercises to improve patients' posture as well as strengthening exercises of the shoulder girdle. However, it is difficult to compare the different studies because the diagnostic criteria are seldom mentioned, the severity of the symptoms varies, and rarely is the type of therapy described.

Procedures

During the last 25 years, I have recommended and used a multidisciplinary approach [10]. The therapy itself starts with shoulder exercises, the purpose of which is to restore the movement of the whole shoulder girdle and to provide more space for the neurovascular structures. Restoration of the movement and function of the cervical spine follows. The exercises that aim to activate the anterior, middle, and posterior scalene muscles are the most important part (Fig. 115.4). These exercises have been shown to correct any malfunction of the first ribs, thus normalizing the function of the upper thoracic aperture [26] and enabling normal movement of the first ribs. Stretching of the muscles of the shoulder girdle involves the upper part of the trapezius muscles, the

sternocleidomastoid muscles, the levator scapulae, and the small pectoral muscle. The role of the small pectoral muscle has been emphasized elsewhere [27]. Further stretching exercises should be administered as needed, depending on the clinical findings in the individual case. Strengthening exercises for the anterior serratus muscle should be included, thus enhancing the stability of the scapula. Nerve gliding exercises are used to restore the mobility of the nerves. It is mandatory that physiotherapists, psychologists, occupational therapists, and social workers be consulted during the whole process. The patients should be observed for a long time because relapses are common. With use of this program, I found that 88.1% of the patients were satisfied with the outcome, that is, their symptoms had either disappeared or were much abated or the real cause of the symptoms had been diagnosed.

Recommendations were carried through during a 2-year follow-up period in 87.9% of cases. Of the patients who were advised to retire because of symptoms, the primary problem was found to be other than thoracic outlet syndrome (psychiatric causes, complex regional pain syndrome, polyneuropathy, multiple sclerosis, other) [10]. Conservative therapy is the treatment of choice in thoracic outlet syndrome because it is safe and can be implemented as a self-treatment program.

If symptoms are not abated despite restored function, the differential diagnosis should be reviewed. The fact that conservative treatment is tedious and relapses are common should not be considered a reason for surgical intervention. Surgery is a viable option only if there are signs of significant

FIGURE 115.4 Normal function of the first ribs and the upper aperture can be achieved by activation of the scalene muscles by the patient. **A**, The patient first activates the anterior scalene muscles by pressing the forehead against the palm, with the cervical spine being all the time in a neutral position. **B**, The middle scalene muscles are activated by pressing sideways against the palm. The exercises are done five or six times for a duration of 5 seconds each and with about 15 seconds between the exercises. The exercises are done on both sides. (Reproduced with permission of Kustannus Oy Duodecim.)

motor loss, atrophy, or vascular thrombosis. Psychosocial aspects should always be taken into account. It is extremely important to evaluate the degree of disability that thoracic outlet syndrome symptoms cause in relation to the patient's life situation and psychosocial abilities.

There is a link between the workplace and the individual in the pathogenesis and course of thoracic outlet syndrome. The role of occupational factors must be considered, and one has to go back to "the scene of the crime."

Surgery

Cherington [28] stated already in 1991, "It is important for surgeons and primary care physicians to be aware of the rising tide of skepticism surrounding the diagnosis and treatment of the thoracic outlet syndrome." Skepticism is indeed justified for several reasons. The most often diagnosed and surgically treated form of thoracic outlet syndrome in the United States, disputed neurologic thoracic outlet syndrome, has no objective clinical, radiologic, or electrodiagnostic criteria. In 1927, Adson [12] introduced scalenotomy as an approach to relieve structures from compression. Roos [1] presented a transaxillary resection of the first rib, and this operation has perhaps been the most used approach. Supraclavicular approaches have also been presented. Some authors claim the results of surgical management to be good, excellent, or favorable in more than 90% of patients [29]. Different studies, however, are difficult to compare because of the various criteria used to assess the outcome. In addition, the numbers of patients have ranged from 26 to 1336 and the follow-up times from 1 month to 15 years. Some authors do not state the follow-up time at all. A combined surgical treatment using transaxillary first rib resection and transcervical scalenotomy is said to be more effective than either of these alone [30]. There have been only a couple of studies in which the follow-up examination was done by independent examiners not involved in the surgical procedure or selection of the patients. This seems to affect the results after surgery. Among the different operative procedures, scalenotomy seems to speed up patients' retirement [31]. Cuetter and Bartoszek [32] and Lindgren [18] have re-evaluated patients treated unsuccessfully with surgery for thoracic outlet syndrome; they found that in each case, another disease or functional disturbance explained the patient's complaints.

Recurrence after unsuccessful procedures may be a disabling and difficult problem for patients. This is extremely tragic in patients who have been found to have pulse changes in provocative positions in the absence of any other symptoms. Even abnormal electrodiagnostic findings before an operation do not predict the outcome of surgery [33]. Clinical tests show a good sensitivity but a poor specificity and cannot be used as the predictors for the outcome after surgery [34]. Long-term results of operation for thoracic outlet syndrome may be much worse than those initially achieved. Patients who present with poorly systematized neurologic symptoms have poor results after surgery and should be denied surgery or at least informed that postoperative results may be disappointing [35].

Botulinum chemodenervation of the scalene muscles has been found useful in alleviating symptoms in patients with

thoracic outlet syndrome, especially if they are waiting for definitive surgical decompression. However, a randomized trial showed that chemodenervation did not result in clinically or statistically significant improvement in pain, paresthesias, or function in a population with thoracic outlet syndrome [36].

Potential Disease Complications

It is very important to detect those patients with post-traumatic thoracic outlet syndrome. These may present with worsening of the symptoms, such as a decrease in muscle strength, increase of pain, and tingling in the radicular territory, as well as unspecific disturbances, such as dizziness and face pain. In the case of these patients, one must consider surgical options [23]. It has been said that true neurogenic thoracic outlet syndrome is rare. Overdiagnosis of this syndrome results from a failure to realize that a wide range of symptoms occur regularly in patients with carpal tunnel syndrome and that these are commonly outside the anatomic distribution of the median nerve. The failure to recognize this can reinforce abnormal behavior in patients, particularly when they are subjected to unnecessary brachial plexus or ulnar nerve surgery, undertaken without neurophysiologic identification of an appropriate neurogenic abnormality [37]. If they are not dealt with correctly, these patients will suffer for long periods with more than one symptom. These may include muscle atrophy, swelling in the supraclavicular fossa, abnormal posture, and tendency to faint with certain movements. The leading symptom is numbness and clumsiness of the hand, but pain in the occiput-shoulder area is an important symptom too [38]. These may worsen without proper therapy.

Potential Treatment Complications

Surgery for thoracic outlet syndrome is not as innocuous as it was once thought. Dale [39] found that more than half of those who reported performing the surgery had encountered brachial plexus injuries severe enough to produce clinical weakness, nearly one fifth of which were permanent. Large numbers of failed thoracic outlet syndrome surgery have been reported during the last decades. Brachial plexus lesions, infections, and cases of life-threatening hemorrhage have been published. Even deaths have been reported. Franklin and colleagues [40] reported that 60% of workers were still work disabled 1 year after thoracic outlet syndrome decompression surgery.

Costochondral junction syndrome
Thoracochondralgia
Chondropathia tuberosa
Costal chondritis

ICD-9 Code

733.6 Tietze's disease; costochondral junction syndrome and costochondritis

ICD-10 Code

M94.0 Chondrocostal junction syndrome (Tietze)

Definition

Tietze syndrome is a benign, self-limited, nonsuppurative localized painful swelling of the upper costal cartilages of unknown etiology [1–10]. It affects the costochondral, costosternal, or sternoclavicular joints [2,5–7,9]. The manubriosternal and xiphisternal joints are less frequently affected [5,10]. First described in 1921 by a German surgeon in Breslau, Alexander Tietze, it is different from the costosternal syndrome [5–12]. Tietze syndrome is a rare cause of benign anterior chest wall pain associated with local swelling of the involved costal cartilages (Fig. 116.1) [5,6,12]. It is typically described in young adults and is a disease of the second and third decades of life [10,12]. Although it is not common, Tietze syndrome may also appear in children, infants [10,13], and elderly people [14]. It affects both men and women in a 1:1 ratio [4–6,9,10,15]. Lesions are unilateral and single in more than 80% of patients [4,10], and the second and third costal cartilages are most commonly involved [1,4,6,9–12]. Costosternal syndrome, a frequent

cause of benign anterior chest wall pain, is not associated with a local swelling of the involved costal cartilages [5–12]. Costosternal syndrome usually occurs during and after the fourth decade of life, more frequently in women in a rate of 2 to 3:1 [9,10]. Multiple costal cartilages are involved in 90% of patients with costosternal syndrome [5,9,10].

The pathogenesis of Tietze syndrome is unknown [1–4,6,8–10]. Recurrent functional overloading or microtrauma to the costal cartilages from severe coughing, heavy manual work, and sudden movement of the rib cage as well as malnutrition, sprain of the intra-articular sternocostal ligament, and respiratory tract infections may influence the development of Tietze syndrome [2,5,6,8–10,12,15]. Costal swelling may be due to focal enlargement [4,7], ventral angulation or irregular calcification of the affected costal cartilage [4,16], and thickening of overlying muscle [16,17]. Tietze syndrome may mimic a variety of life-threatening clinical entities [4,6,15] and must be considered in the differential diagnosis of any painful mass in the peristernal area. Clinical awareness of this syndrome and of its benign course may minimize performance of invasive diagnostic procedures [13].

Symptoms

Clinical manifestations include the sudden or gradual onset of pain of variable intensity [3,4,10,15] in the upper anterior chest wall in association with a fusiform and tender swelling of the involved costal cartilage [4,15]. Despite descriptions that pain may radiate to the shoulder, arm, and neck [3,4,12], its distribution usually occurs within the segment innervated by the afferent fibers carrying the painful impulse [2]. It is often aggravated by motion of the thoracic wall, sneezing, coughing, deep breathing, bending, exertion [1–8,15], and lying prone or over the affected side [10]. Some patients report inability to find a comfortable position in bed and have pain on turning over in the bed [1]. Weather change, anxiety, worry, and fatigue may exacerbate the pain [4]. Symptoms are usually unilateral, with no preferential side [3]. There is no reported association with sternotomy.

Physical Examination

On physical examination, a slight firm swelling is noted at the involved site [1–4,15]. Systemic manifestations [4,6,10,13,15] and inflammation are usually absent [1,4,5,7,10,15], but

FIGURE 116.1 Schematic representation of the area of Tietze syndrome (costal cartilage, costosternal and costochondral joints) and anatomic relations with the mediastinal structures and other anterior chest wall structures.

there may be local heat [15]. Pain is reproduced with active protraction or retraction of the shoulder, deep inspiration, and elevation of the arm [12] (Fig. 116.2). A unique visible, spherical, nonsuppurative, tender tumor of elastic-hard and pasty consistency can be palpated, usually over the second and third costochondral joints. Local palpation with firm pressure over the localized tender swelling reproduces the spontaneous pain complaint [12] (Fig. 116.3). Physical examination findings of the musculoskeletal and neurologic systems of reported cases from the literature are usually normal except for the local findings [4–6,13,15,17]. Muscle strength and upper limb range of motion may be decreased because of pain. Dermatomal and subcutaneous hyperalgesia (Fig. 116.4) and hyperemia (Fig. 116.5) may be present in the involved thoracic spinal segments. The adjacent intercostal [12], sternal, and pectoralis major and minor muscles may be tender to palpation [14].

FIGURE 116.2 Reproduction of the spontaneous pain complaint during arm elevation in a patient diagnosed with Tietze syndrome.

Functional Limitations

The disability produced by Tietze syndrome is usually minor, although it can be severe with activity restriction involving the trunk and upper limbs. Activities such as lifting, bathing, ironing, combing and brushing hair, and other activities of daily living can be problematic. Patients who have physically vigorous jobs may need to be put on light duty for weeks and avoid physical efforts of the upper limbs and trunk [1]. Functional limitations may also be due to chronic pain [18]; however, even of those patients who continue to have pain after 1 year, most lead a life without disability.

Diagnostic Studies

Diagnosis of Tietze syndrome is essentially made on a clinical basis: anterior chest wall pain confirmed by palpation of a tender swelling at the second or third costochondral junction that reproduces the patient's complaint in the absence of another definite diagnosis [3–5,7–9,11,15]. Results of laboratory analysis including inflammatory and immunologic parameters are usually normal [4–9,15]. Some cases may show a slight increase in the erythrocyte sedimentation rate [7,13,15].

Chest, rib, and sternum plain films and conventional tomograms of the costochondral junction are generally normal [6,17,19]. Plain radiographs may show cartilage enlargement on tangential views, chondral calcification, irregularities at the joint surface, osteosclerosis, and presence of osteophytes at the costal joint. However, these radiographic changes may also be found in physiologic costochondral calcifications [20]. Plain radiographs are therefore mainly indicated to rule out occult bone diseases including tumors, low-grade infections, tender fat or lipomas, chest wall contusion, and congenital deformity [4,12,16]. Tuberculosis, chondroma, and chondrosarcoma are mostly located at the costochondral junction [16].

Ultrasonographic findings of the affected costochondral joints are characterized by an increase of the size of the

FIGURE 116.3 Local palpation with firm pressure over the localized tender swelling reproduces the spontaneous pain complaint.

FIGURE 116.5 Hyperemia localized at the involved thoracic spinal segments after the pinch and roll maneuver.

FIGURE 116.6 Comparison of the ultrasonographic findings of the affected costochondral joint (*left*) and the nonaffected contralateral joint (*right*) in an 82-year-old woman diagnosed with Tietze syndrome. The affected costochondral joint appears with a discrete increased size and as a nonhomogeneous hyperechoic cartilage with dotty, hyperreflective echoes and broad posterior acoustic shadows. (Courtesy Marcelo Bordalo Rodrigues.)

affected costal cartilage compared with the contralateral symmetric joint and normal age- and gender-matched controls (Fig. 116.6) [21]. There is also a nonhomogeneous increase in the echogenicity in the diseased cartilage, with dotty, hyperreflective echoes and intense broad posterior acoustic shadow [21]. The normal ultrasonographic picture of the costal cartilage (Fig. 116.7) is manifested as a hypoechoic oval area with the absence of posterior acoustic

FIGURE 116.7 Normal ultrasonographic appearance of the costal cartilage. The normal costal cartilage appears as the homogeneous hypoechoic oval area between the sternum and the costal arch. (Courtesy Marcelo Bordalo Rodrigues.)

shadows in the longitudinal scans [21], and it appears as a ribbon-shaped homogeneous hypoechogenicity in the transverse scan with no posterior acoustic shadowing [21].

Computed tomography of the chest is an effective noninvasive means of imaging costal cartilage and adjacent structures in patients with Tietze syndrome [17,19,21]. Costal cartilage is normally symmetric in size and orientation at any level and is normally oriented along the horizontal axis [17]. Cartilage density is uniform and greater than that of the overlying muscle but less than calcium density [17]. Reported computed tomographic abnormalities of patients with Tietze syndrome include focal enlargement of the involved costal cartilage [6,17,19], ventral angulations [6,15,17,19], swelling or irregular calcification of the affected costal cartilage [17,19], perichondral soft tissue swelling, and periarticular bone sclerosis [5,22]. Computed tomography scan is useful to exclude other possible causes of chest wall or thoracic mass [6], such as malignant lymphoma [17,23] and mediastinal carcinoma [24]. Fluorodeoxyglucose–positron emission tomography can also be used in the differential diagnosis with malignant neoplasms [25].

Asymmetric thickening of the pectoralis major muscle simulating a chest wall mass can also be excluded [17]. Planar bone scanning with technetium Tc 99 usually reveals intense tracer uptake, but the findings are not specific [4,6,15,20,22]. Bone scintigraphy allows the precise localization of the involved joint [6] and the delineation of the number of involved joints; it should be considered to rule out occult fractures of the ribs and sternum in cases of local trauma [12].

Pinhole skeletal scintigraphy seems to enhance diagnostic specificity [20]. It is able to show a characteristic appearance of a drumstick-like pattern in acute cases and a C- or inverted C-shaped uptake in the chronically affected costal cartilage [20].

Magnetic resonance imaging of the costosternal and sternoclavicular joints usually shows thickening at the site of complaint; focal or widespread increased signal

intensities of affected cartilage on both T2-weighted and short T1 inversion recovery or fat-saturated images; bone marrow edema in the subchondral bone; and intense gadolinium uptake in the areas of thickened cartilage, in the subchondral bone marrow, or in capsule and ligaments [26]. Magnetic resonance imaging is also indicated if an occult mass is suspected [9,12]. Magnetic resonance imaging allows differentiation of cartilage and bone abnormalities [26].

The histopathologic characteristics of costal cartilage in Tietze syndrome are usually normal [15] or nonspecific [3,6,7,15]. These characteristics include increased vascularity and degenerative changes with patchy loss of ground substance leading to a fibrillar appearance [6,22,27]. Degenerative changes occur with the formation of clefts, which may undergo calcification [1,22,27].

Differential Diagnosis

ANTERIOR CHEST WALL PAIN OF LOCAL ORIGIN

Costosternal syndrome

Trauma: dislocation and fractures of the ribs, sternum, clavicle, costal cartilage, costochondral or sternoclavicular joint

Arthritis: osteoarthritis, rheumatoid arthritis, ankylosing spondylitis, Reiter syndrome, psoriatic arthritis, SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, osteitis), gout

Infection: osteomyelitis, low-grade infection of the costal cartilage (tuberculosis, syphilis, typhoid and paratyphoid infections, blastomycosis, actinomycosis, brucellosis)

Tumors of the costochondral cartilages

Benign: chondroma, multiple exostosis, lipomas

Malignant neoplasms: Hodgkin and non-Hodgkin

lymphoma [28], metastatic bone diseases (carcinoma of breast, lung, thyroid, kidney, or prostate), multiple myeloma, plasmacytoma, thymoma, chondrosarcoma

Myofascial pain syndrome at the anterior chest wall:

sternal, pectoralis major, pectoralis minor, scalene, sternocleidomastoid (sternal head), subclavius, iliocostalis cervicis muscles

Other: slipping rib syndrome, condensing osteitis of the clavicle, congenital sternoclavicular malformations, xiphoidalgia syndrome, T1-T12 radiculopathy, intercostal neuritis (postherpetic neuralgia)

ANTERIOR CHEST WALL PAIN OF VISCERAL ORIGIN

Cardiac: myocardial infarction, angina pectoris, stenocardia

Pulmonary: pneumonia, pulmonary embolism, pleurisy, lung abscess, atelectasis, spontaneous pneumothorax

Breast: cyclic breast pain, duct ectasia, breast carcinoma

Abdominal: peptic duodenal ulcer, epigastric hernia, gastritis or pancreatitis, acute cholecystitis, diffuse peritonitis

Treatment

Initial

Treatment is symptomatic because the pathogenesis of the disease is still unclear [3,4,6,14,15]. The natural history of patients diagnosed with true Tietze syndrome is, in general, good and benign because of the self-limited characteristic of the condition. In the majority of cases, pain disappears spontaneously within a few weeks and swelling in a few months [15] without treatment [9]. Symptoms may be exacerbated after manual work and severe cough. During

this period, the use of an elastic rib belt may also provide symptomatic relief and help protect the costosternal joints from additional trauma [9,12]. Initial treatment of the pain and functional disability associated with Tietze syndrome should include simple oral analgesics such as acetaminophen, oral or topical nonsteroidal anti-inflammatory drugs (NSAIDs) alone [6,9,11,14] or in combination with codeine [5,8,9,15], or tramadol. Reassurance about the benign nature of the disorder and the diagnosis of a non-life-threatening but real and well-recognized musculoskeletal pain disease can often by itself reduce the anxiety and fears and lead to symptomatic pain relief [2–5,8–11,15,29]. Avoidance of iatrogenic worries is usually helpful [29]. Removal of aggravating and perpetuating factors (including physical efforts of the upper limbs and trunk, chronic cough, and bronchospasm) and improved nutrition are also important [1,5,8,9,14]. Human calcitonin at the dosage of 0.25 mg/day was given for a course of 1 month to five women diagnosed with Tietze syndrome who had intense pain not relieved by conventional treatment [30]. Three patients reported complete remission of symptoms and imaging findings, and symptoms improved in two patients with disappearance of pain [30].

Rehabilitation

Physical modalities including local superficial heat for 20 minutes, two or three times a day, and ice for 10 to 15 minutes, three or four times a day, can be performed until symptoms are improved [3,12,14]. Heat and cold are equally effective, and the choice of modality relies on the patient's preference and tolerance. Transcutaneous electrical nerve stimulation and electroacupuncture may be applied over the painful area [14]. Electroacupuncture is applied by introducing the acupuncture disposable needle over the skin points of lower electrical skin resistance [14] that are located within the involved spinal segments. Galvanic or faradic low-frequency electrical currents are applied at the inserted needle [14]. Administration of corticosteroids by iontophoresis may provide more prolonged pain relief [11]. Gentle, pain-free range of motion exercises should be introduced as soon as tolerated [12]. Vigorous exercises should be avoided if they exacerbate the patient's symptoms [12]. Proper posture during sitting or working activities should be restored [5,8,9]. Inactivation of associated pectoralis major trigger points followed by relaxation and stretching exercises with relaxation of the involved muscles may also be helpful. Stretching exercises of the pectoralis major muscle, such as the standing pushup in the corner for 10 seconds, repeated for 1 or 2 minutes several times a day, may be helpful [8,31]. Vapocoolant spray applied to the involved areas may also relieve chest wall pain [8]. Patients should be instructed to avoid improper posture or repetitive misuse of chest wall muscles [8].

Psychological and psychopharmacologic treatment should be considered for patients with continuing symptoms and disability, especially if these are associated with abnormal health beliefs, depressed mood, panic attacks, or other symptoms such as fatigue or palpitations [29]. Both cognitive-behavioral therapy and selective reuptake inhibitors have

been shown to be effective [29]. Tricyclic antidepressants are helpful in reducing reports of pain in patients with chest pain and normal coronary arteries [29].

Procedures

Most patients respond to NSAIDs, heat, and activity modification. For patients who do not respond to the initial and rehabilitation treatment modalities, however, a local anesthetic [2,4,6] and steroid injection can be performed as the next symptom control maneuver [2,5,6,8,9,11,12,15,21]. Injection of the costal cartilage is performed by placing the patient in the supine position [12,21]. Proper preparation with antiseptic solution of the skin overlying the affected costal cartilage is carried out with isopropyl alcohol and soluble iodine solution to swab the injection site [21]. The exact position for injection is identified by clinical and ultrasonographic examination [21]. The injection site is the point of maximum tenderness by palpation or the point of maximum cartilaginous hypertrophy by ultrasonographic examination [21]. A refrigerant spray may be used to anesthetize the overlying skin before the needle is inserted [21]. There should be limited resistance to injection [12]. If significant resistance is found, the needle should be withdrawn slightly and repositioned until the injection proceeds with only limited resistance [12]. This procedure should be repeated for each affected joint [12]. After the needle is removed, a sterile pressure dressing and ice pack are placed at the injection site [12]. Local steroid injections associated with local anesthetics have shown good therapeutic results [21]. There is an average of 82% decrease in the size of the affected costal cartilage 1 week after the local anesthetic and steroid injection, and the posterior acoustic shadowing is absent [21]. Clinical examination of the injected patients detected complete resolution and substantial improvement of signs and symptoms of pain and swelling. This shows a strong correlation between clinical changes and ultrasonographic findings in patients with Tietze syndrome. An intercostal nerve block performed 1.5 to 2 inches proximal to the costochondral joint of the affected level provides even longer lasting pain relief and is indicated if other measures are not effective [11].

Surgery

Surgical procedures are rarely necessary and indicated only if the symptomatic conservative measures failed to alleviate symptoms [9]. Surgical excision of the localized involved cartilage can be performed in severe and refractory cases [9]. Costosternal or sternoclavicular arthrodesis may be performed if conservative measures fail to provide satisfactory results.

Potential Disease Complications

Tietze syndrome is a benign condition and rarely presents complications. It is self-limited with spontaneous recovery of the pain after a few weeks or several months [1,3,4,15] to 1 year in the majority of cases. Swelling may persist for months [15] to years [4]. The course of this condition is characterized by periods of recurrence and improvement [1,3,4,14].

Potential Treatment Complications

The systemic complications of NSAIDs are well known and most commonly affect the gastric, hepatic, and renal systems. The major complication of the local steroid combined with local anesthetic injections is pneumothorax if the needle is placed too laterally or deeply and invades the pleural space [12]. Cardiac tamponade as well as an iatrogenic infection, although rare, can occur if, respectively, the needle is placed in the direction of the heart and strict aseptic techniques are not performed [12]. The possibility of trauma to the contents of the mediastinum remains another possibility [12]. This complication can be greatly decreased if the clinician pays close attention to accurate needle placement [12] or performs the injection with ultrasound guidance [21].

ICD-10 Code

G50.0 Trigeminal neuralgia, tic douloureux, trifacial neuralgia, syndrome of paroxysmal facial pain

Definition

Trigeminal neuralgia is pain in the distribution of the trigeminal dermatomes. The pain is described as an electric shock–like, stabbing, unilateral pain having abrupt onset and termination. Intervals between attacks are pain free. Non-noxious triggers occur in the same or different sensory areas of the face, and there is minimal or no sensory loss in the region of pain [1–7]. Trigeminal neuralgia has an incidence of 4 or 5 per 100,000 people up to 20 per 100,000 per year after the age of 60 years [7–9] and a prevalence of 0.1 to 0.2 per 1000. The female-to-male ratio is about 3:2 [8].

The trigeminal nerve (cranial nerve V) is the largest of the cranial nerves. It begins in the brainstem at the trigeminal nucleus and travels along the ventrolateral surface of the pons and through the subarachnoid space until it enters the temporal bone, where it forms into the gasserian ganglion located in the Meckel cave [10]. The divisions are the ophthalmic or V1 branch, the maxillary or V2 branch, and

the mandibular or V3 branch (Figs. 117.1 and 117.2). The relative distribution of pain in trigeminal neuralgia is as follows: V1, 20%; V2, 44%; V3, 36% [10].

Most patients with classic symptoms have mechanical compression of the trigeminal nerve as it leaves the pons and travels in the subarachnoid space toward the Meckel cave [10–12]. Most commonly, there is cross-compression by a major vessel. Other proposed causes include demyelinating plaques from multiple sclerosis, neoplastic disease, and abscess formation with bone resorption and irritation of the trigeminal nerve in the maxilla or mandible. Trigeminal neuralgia occurs in about 1% of patients with multiple sclerosis, and approximately 2% to 8% of patients with trigeminal neuralgia have multiple sclerosis [7,8,13].

Regardless of the etiology, it is likely that both peripheral and central mechanisms play a role in the pathogenesis of this syndrome.

Symptoms

Typical trigeminal neuralgia symptoms involve electric shock–like pain in the distribution of one or more branches of the trigeminal nerve. Pain is often intermittent, with pain-free intervals of months or even years [10]. The pain may last a few seconds to less than 2 minutes. The pain has at least four of the following five characteristics: distribution along one or more divisions of the trigeminal nerve; sudden intense, sharp, superficial, stabbing, or burning quality; severe intensity; precipitation from trigger areas or by certain daily activities, such as eating, talking, washing the face, or cleaning the teeth; and between paroxysms, the patient is completely asymptomatic [6,14]. In general, patients do not report any other neurologic deficit.

Physical Examination

The diagnosis of trigeminal neuralgia is made primarily by history. The Sweet criteria for this diagnosis are five pain descriptors. The diagnosis must be questioned if these criteria are not met [5], as follows: the pain is paroxysmal; the pain may be provoked by light touch to the face (trigger zones); the pain is confined to the trigeminal distribution; the pain is unilateral; and the findings on clinical sensory examination are normal [5,15]. When possible, physical

examination of the oral cavity, dentition, and trigeminal nerve distribution should be performed to rule out other diseases. A complete cranial nerve examination should be performed. In general, no sensory or motor deficits are present, but serial examinations may detect a change and identify a secondary cause of trigeminal neuralgia [6].

FIGURE 117.1 Dermatomes for trigeminal nerve. V1, ophthalmic nerve. V2, maxillary nerve. V3, mandibular nerve. (From Waldman SD. *Trigeminal nerve block: coronoid approach*. In Waldman SD, ed. *Atlas of Interventional Pain Management*, 2nd ed. Philadelphia, WB Saunders, 2004.)

Functional Limitations

In general, there are no impairments associated with trigeminal neuralgia. However, the pain from this entity may result in significant limitation in several activities of daily living. During exacerbations, patients may be functionally incapacitated because of pain and may be unable to perform activities such as comb hair, chew food, or shave. Talking on the telephone may be painful. Wearing glasses or makeup may not be possible. The pain from trigeminal neuralgia is not continuous but paroxysmal, suggesting spontaneous discharges from specific neurons, and it frequently occurs by innocuous tactile stimuli [4]. Therefore any activity that involves contact with the face may become difficult or impossible.

Diagnostic Studies

When a diagnosis of trigeminal neuralgia is suspected, patients should have diagnostic brain imaging with magnetic resonance imaging. Magnetic resonance imaging with gadolinium contrast can aid in diagnosis of multiple sclerosis plaques, neoplasm, and any neurovascular compressive relationship to the trigeminal root [5]. Electromyography, nerve conduction studies, and quantitative sensory testing may provide sensitive, quantitative, and objective results for the diagnosis, localization, and accuracy of damage to the trigeminal nerve [16]. Other studies that may have a role in diagnosis include intraoral, skull, and sinus radiographs and daily diaries of pain.

Differential Diagnosis

See [Table 117.1](#).

FIGURE 117.2 Anatomy of trigeminal nerve. The gasserian ganglion is formed from two roots that exit the ventral surface of the brainstem at the midpontine level. These roots pass in a forward and lateral direction in the posterior cranial fossa across the border of the petrous bone. They then enter the Meckel cave. The gasserian ganglion has three sensory divisions, the ophthalmic (V1), the maxillary (V2), and the mandibular (V3). (From Waldman SD. *Gasserian ganglion block*. In Waldman SD, ed. *Atlas of Interventional Pain Management*, 2nd ed. Philadelphia, WB Saunders, 2004.)

Table 117.1 Differential Diagnosis of Trigeminal Neuralgia or Facial Pain

Condition	Prevalence	Major Location and Radiation	Timing	Character and Severity	Provoking Factors	Associated Factors
Dental						
Pulpal	Very common	Well localized to a tooth	Can last 10-20 minutes after sugary stimulus	Sharp, stabbing, throbbing, dull, moderate to severe	Hot, cold, or sweet foods provoke it, rarely spontaneous	Immediate relief on removal of stimulus
Fractured or cracked tooth	Fairly common	Localized to one or two teeth, but may be poorly localized, difficult to visualize	Very short lasting, seconds, intermittent	Sharp, moderate	Biting, never spontaneous, may be sensitive to heat	Rebound pain, worse after force removed, opposing natural tooth normally present
Pulpal—chronic pulpitis	Common	Poorly localized intraorally	Intermittent, hours	Mild, dull, throbbing	Occasionally heat	Often large restoration
Periodontal—chronic apical periodontitis	Common	Poorly localized, intraoral	Intermittent, minutes to hours	Mild, dull, throbbing	Large restoration	Sinus may be visible, bad taste
Bone pain—osteomyelitis	Rare	Most often mandible, widespread	Continuous	Throbbing, severe	Biting on mobile teeth	Pyrexia, malaise, trismus, swelling, may be paresthesia, pus, mobile teeth, sequestra
Denture pain, pressure on mental nerve, secondary trigeminal neuralgia	Rare	Localized intraoral	Intermittent, daily	Aching, may be sharp if over mental nerve	Eating with denture	Often redness, ulceration in area of pressure
Neurologic Trigeminal Neuralgia						
Classic, typical [14]	Rare	Intraoral or extraoral in trigeminal region	Each episode of pain lasts for seconds to minutes; refractory periods and long periods of no pain	Sharp, shooting, moderate to very severe	Light touch provoked (e.g., eating, washing, talking)	Discrete trigger zones
Atypical trigeminal neuralgia [17]	Rare	Intraoral or extraoral in trigeminal region	Sharp attacks lasting seconds to minutes, more continuous-type background pain, less likely to have complete pain remission	Sharp, shooting, moderate to severe but also dull, burning, continuous mild background pain	Light touch provoked, but continuous-type pain not so clearly provoked	May have small trigger areas, variable pattern
Trigeminal neuropathy [18]	Very rare	Trigeminal area, but may radiate beyond	Continuous	Dull with sharp exacerbation	Areas of allodynia, light touch	Sensory loss, subjective-objective, progressive, vasodilation and swelling may occur

Glossopharyngeal neuralgia	Very rare	Intraoral in distribution of glossopharyngeal	Each episode lasts for seconds up to 2 minutes	Sharp, stabbing, burning, severe	Swallowing, chewing, talking	No neurologic deficit
Postherpetic neuralgia [19]	Rare	Most commonly first division of trigeminal	Continuous pain	Tingling, severity varies	Tactile allodynia	More than 6-12 months after acute herpes zoster
Vascular						
Cluster headache, episodic pain-free periods, chronic, no remissions [14]	Rare	Orbital, supraorbital, temporal	15-180 minutes to several hours, from 1 every other day to 8 per day	Hot, searing, punctuate, severe	Vasodilators (e.g., alcohol)	Conjunctival injection, lacrimation, nasal congestion, rhinorrhea, sweating, miosis, ptosis, eyelid edema, restlessness
SUNCT [20]	Very rare	Ocular, periocular, but may radiate to frontotemporal area, upper jaw, and palate	Each episode last up to 2 minutes; intermittent, several attacks per day and then may remit	Burning, electrical, stabbing, severe	Neck movements	Conjunctival injection, lacrimation, nasal stuffiness, rhinorrhea
Chronic paroxysmal hemicrania [20]	Very rare	Eye, forehead	Pain lasts 2-45 minutes, 5-10 times daily	Stabbing, throbbing, boring	Head movements, responds to indomethacin	Autonomic symptoms as for SUNCT
Giant cell arteritis [20]	Rare	May be bilateral, mostly over temporal artery	Continuous	Aching, throbbing, boring, sharp	Chewing	Jaw claudication, neck pain, anorexia, visual symptoms; temporal artery biopsy is "gold standard"
Temporomandibular disorders, idiopathic orofacial pain, facial arthromyalgia [19]	Relatively common	May be bilateral, periauricular, radiate to neck, temples	Intermittent, may last for hours, may have severe exacerbations	Throbbing, sharp, or dull aching	Clenching and grinding, opening wide, psychosocial factors, trauma	May be limitation in opening, tenderness of muscles of mastication, altered occlusion, responds to relaxation
Atypical facial pain [21]	Relatively common	May be bilateral or unilateral, can radiate widely beyond trigeminal area, variable location	Intermittent or continuous, often long history of pain	Nagging, throbbing, aching, sharp (wide range of words used), and severity mild to moderate	Life events, stress, weather changes, movements	Dysesthesia, facial edema, headaches, depression
Atypical odontalgia, phantom tooth [19]	Rare	Intraoral in a tooth or teeth, gingival, moves to another area	Continuous, few minutes to hours	Dull, throbbing, may be sharp, mild to moderate	Life events, emotional, teeth hypersensitive to temperature and pressure	Often history of tooth extraction

Treatment

Initial

Treatments that may help with trigeminal neuralgia include heat or cold therapy, massage, avoidance of triggers, and application of transcutaneous electrical nerve stimulation [8,9]. Topical ointments such as lidocaine, ketamine, and ketoprofen may help as well [8,9]. Pharmacologic options are listed in Table 117.2. The anticonvulsant carbamazepine is considered a first-line therapy and has been efficacious in several controlled trials [22–25]. Carbamazepine can be associated with systemic issues affecting the hematologic and endocrine system (see “Potential Treatment Complications”). The carbamazepine derivative oxcarbazepine is associated with fewer side effects and often better tolerated. Baclofen and lamotrigine have also been helpful in controlled trials [22,26,27]. Uncontrolled observations, clinical practice, and the authors’ experience also suggest that phenytoin, clonazepam, topiramate, sodium valproate, gabapentin, pregabalin, zonisamide, levetiracetam, mexiletine, and lidocaine may be useful [22]. Pharmacologic therapy with nonsteroidal anti-inflammatory agents, acetaminophen, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, and muscle relaxants may be useful. One study showed that intranasal lidocaine 8% administered by a metered-dose spray produced prompt but temporary analgesia without serious adverse reactions in patients with second-division trigeminal neuralgia [28]. In general, 80% of patients will respond to medical therapy [7].

Rehabilitation

Modalities for pain control, such as electrical stimulation, ice massage, and hot packs, can play a role in rehabilitation and recovery from trigeminal neuralgia. Speech therapy may be indicated to help with oral motor deficits that affect speech or swallowing.

Adaptive equipment, such as a telephone earset, may be recommended. Some general chronic pain rehabilitation approaches may also be useful, such as improved sleep hygiene, low-intensity aerobic exercise, biofeedback,

cognitive-behavioral therapy, and relaxation techniques. Acupuncture may also have a role in the management of trigeminal neuralgia [29]. After surgical intervention with microvascular decompression, the rehabilitation process is often brief. Trigeminal neuralgia pain relief is usually immediate, and neuropathic medications are gradually discontinued in the weeks after surgery. If pain does recur, medications may be restarted, or if necessary, a second interventional procedure may eventually be needed.

Trigeminal neuralgia patients with underlying multiple sclerosis face many therapeutic challenges. Rehabilitation exercises that improve multiple sclerosis symptoms and quality of life can help modulate the impact of trigeminal neuralgia. Aerobic exercise has been shown to improve quality of life, pain, fitness, and function in multiple sclerosis patients with moderate to severe disability [30].

Procedures

With medically refractory trigeminal neuralgia, physicians and patients can choose among several interventions, such as transient nerve blocks, rhizotomy by radiofrequency (RF) ablation, stereotactic radiosurgery, and surgical microvascular decompression. Local anesthetic trigeminal nerve blocks may reduce the intensity or the episodes of pain (Fig. 117.3), but the pain often outlasts the duration of the local anesthetic. Nerve blocks can be repeated at intervals but are more useful as a diagnostic test to judge candidacy for percutaneous RF ablation [3]. RF ablation is the most common nonsurgical intervention performed for trigeminal neuralgia, with a reported initial success rate of more than 90% [31–33]. However long-term efficacy of RF ablation is lower than that of microvascular decompression, with approximately 20% reporting recurrence of pain within 12 months [31,32,34]. In a review of 1600 RF ablations of the trigeminal nerve, Kanopolat reported the most common side effects to be weakened corneal reflex (5.7%), masseter weakness (4.1%), and dysesthesia (1%) [31]. Regarding specific RF technique, conventional RF was clearly more efficacious than pulsed RF in a double-blind randomized trial of 40 patients with idiopathic trigeminal neuralgia [34].

Stereotactic radiosurgery is another option for trigeminal neuralgia. A focused beam of radiation is used to target the trigeminal nerve root. Success rates of 80% have been reported, but microvascular decompression still offers superior long-term outcomes [33,35,36]. However, both RF ablation and stereotactic radiosurgery are viable alternatives to microvascular decompression, especially for high-risk elderly patients, the patient’s preference to avoid surgery, or prior failed microvascular decompression.

Other forms of rhizotomy have reported good short-term results with neurolytic agents such as alcohol and glycerol. The consensus among most physicians is that these particular techniques have lower success rates and higher morbidity [3].

Surgery

Overall nonsurgical interventions are effective but lack robust long-term efficacy, leading to repeated interventions. Definitive surgical therapy is microvascular decompression, which entails a craniotomy to insert a felt barrier or inert

Table 117.2 Pharmacologic Options for Trigeminal Neuralgia Reported in the Literature

Drug	Daily Dose	NNT
*Carbamazepine	300-2400 mg	1.4-2.1 (1.1-3.9)
*Baclofen	60-80 mg	1.4 (1.0-2.6)
*Lamotrigine	400 mg	2.1 (1.3-6.1)
Phenytoin	300-400 mg	
Clonazepam	6-8 mg	
Valproate	1200 mg	
Oxcarbazepine	1200-1400 mg	
Gabapentin	600-2000 mg	
Intravenous lidocaine	2-5 mg/kg	
Mexiletine	10 mg/kg	

*Indicates data from placebo-controlled trials.

NNT is number needed to treat to obtain 1 patient with at least 50% pain relief.

From Sindrup SH, Jensen TS. Pharmacotherapy of trigeminal neuralgia. Clin J Pain 2002;18:22-27.

FIGURE 117.3 Technique of trigeminal nerve block. The patient is placed in the supine position with the cervical spine in the neutral position. The coronoid notch is identified by asking the patient to open and close the mouth several times and palpating the area just anterior and slightly inferior to the acoustic auditory meatus. After the notch is identified, the patient is asked to hold the mouth in neutral position. A total of 4 mL of local anesthetic is drawn up in a 12-mL sterile syringe. In treatment of trigeminal neuralgia, atypical facial pain, or other painful conditions involving the maxillary and mandibular nerves, a total of 80 mg of depot steroid is added to the local anesthetic. After the skin overlying the coronoid notch is prepared with antiseptic solution, a 22-gauge, 3½-inch styleted needle is inserted just below the zygomatic arch directly in the middle of the coronoid notch. The needle is advanced approximately 1½ to 2 inches in a plane perpendicular to the skull until the lateral pterygoid plate is encountered. At this point, if blockade of both the maxillary and mandibular nerves is desired, the needle is withdrawn slightly. After careful aspiration, 6 mL of solution is injected in incremental doses. During the injection procedure, the patient must be observed carefully for signs of local anesthetic toxicity. (From Waldman SD. *Trigeminal nerve block: coronoid approach*. In Waldman SD, ed. *Atlas of Interventional Pain Management*, 2nd ed. Philadelphia, WB Saunders, 2004.)

sponge between the compressing vessel and trigeminal nerve origin in the cerebellopontine angle cistern. Overall long-term outcomes are excellent, with complete pain relief as high as 70% to 86% several years after surgery [37–39]. Although the elderly have traditionally been considered a higher risk group for microvascular decompression, more recent data from small prospective studies indicate that some older patients can safely undergo microvascular decompression [38,39].

Furthermore, although it is still experimental, intracranial neurostimulation provides an alternative means for trigeminal neuralgia pain relief in surgically and medically refractory cases. By implantation of electrodes to the facial motor cortex, motor cortex stimulation has shown efficacy for neuropathic facial pain. Motor cortex stimulation has shown particular promise in the treatment of trigeminal

neuropathic pain and central pain syndromes, such as thalamic pain syndrome [40].

Potential Disease Complications

Trigeminal neuralgia is generally amenable to surgical treatment or pharmacotherapy. However, it can progress to become a chronic intractable pain syndrome. In refractory cases, it is important to consider other diagnoses or facial pain syndromes.

Potential Treatment Complications

Carbamazepine can be associated with numerous side effects, including aplastic anemia and the syndrome of inappropriate diuretic hormone secretion; hence, frequent monitoring is necessary. Our practice is to check a CBC and chemistry panel 2 weeks after starting the medication, monthly for 3 months, and then every 6 to 9 months thereafter. If the patient is on a stable dose and a dose adjustment is made, we recheck the labs within 1 month after the dose change. For Gamma Knife radiosurgery, post-treatment facial numbness was reported as bothersome in 5%, commonly in patients who underwent another invasive treatment [36]. Although microvascular decompression has the best efficacy and durability of all treatments, known complications can be serious and include up to a 4% risk of cerebellar hematoma, cranial nerve injury, cerebrospinal fluid leak, stroke, and death—complications not seen with the less invasive ablative procedures [41]. In addition, in a case series of 67 elderly patients undergoing posterior fossa exploration for trigeminal neuralgia, complications occurred in 10 patients (15%) and included ataxia (10%), hearing loss (5%), trigeminal dysesthesias (5%), facial weakness (3%), aseptic meningitis (2%), and pulmonary embolus (2%) [39].

Z44.022 Encounter for fitting and adjustment of partial artificial left arm

Z44.029 Encounter for fitting and adjustment of partial artificial unspecified arm

Definition

Upper limb amputations are devastating occurrences for individuals, with profound functional and vocational consequences. In the United States, overall, there are approximately 1.7 million people living with a limb loss, or approximately 1 of every 200 people [1]. In contrast to lower limb loss, upper extremity amputation is much less frequent, affecting approximately 41,000 persons, or about 3% of the U.S. amputee population [2]. The primary reason for upper limb loss is trauma; cancer is the next most common reason [2–4]. The rates for traumatic amputations declined by 50% during the period 1988 to 1996 [3], probably because of changing work force patterns and greater concerns for industrial safety. However, as a result of the recent wars in Afghanistan and Iraq, the number of catastrophic injuries due to explosive devices has increased [5]. Traumatic amputation is the major reason for upper extremity loss in the military [5]. As of September 2010, 21% of major limb loss sustained in Operation New Dawn, Operation Iraqi Freedom, and Operation Enduring Freedom involved the

upper extremity [5,6]. As of September 2010, there were 1219 major limb and 399 partial limb amputations [6].

Upper limb amputations from trauma occur at a rate of 3.8 individuals per 100,000; finger amputations are the most common (2.8 per 100,000). Hand amputations from trauma occur at a rate of 0.02 per 100,000 [3]. Traumatic transradial amputations occur at a rate of 0.16 per 100,000 persons, and transhumeral limb loss from trauma occurs at a rate of 0.1 per 100,000 [3].

Limb amputations that result from malignant neoplasms have declined approximately 42% from 1988 to 1996 [3]. Their rates of occurrence are lower than for trauma, with an upper limb loss rate in 1996 of 0.09 per 100,000 [3]. These rates of upper limb amputations are lower than the incidence rates of lower limb dysvascular amputations due to diabetes and peripheral arterial diseases, which occur in 45 per 100,000 individuals and disproportionately affect minority individuals [3,7].

In an analysis of the National Trauma database between the years 2000 and 2004, upper limb amputations were more likely to be seen than lower limb amputations in motor vehicle crashes. Motorcyclists and pedestrians were more likely to sustain a lower limb amputation [8]. Machinery, power tools, explosions, self-inflicted injury and assaults, and power tools are among the most common reasons for traumatic upper limb amputations [8]. Electrical burn is an uncommon cause of upper extremity amputation. Heating causes coagulative necrosis, and the passage of the electrical current through the tissues causes disruption of cell membranes [9]. Men are at far greater risk for traumatic amputation than women are, demonstrating about 6.6 times the female rate for minor amputations of the finger and hand [4].

Traumatic amputations often result in irregularly shaped residual limbs and frequently require skin grafts. Efforts to reduce edema and to promote proper limb shaping should be instituted as soon as possible [10]. The level of amputation is the single most important determinant of function after amputation. The primary surgical principle is to save as much limb as possible while ensuring removal of devitalized tissues and residual limb wound healing. Saving of the most distal joint possible dramatically improves the amputee's function. The elbow joint, for instance, when it is preserved, allows the arm to function in carrying and supporting activities. For the mangled hand, saving of any fingers or remnants provides reconstructive hand surgeons the possibility of constructing a hand that can perform grasping activities.

Rates of prosthetic rejection are high among upper limb amputees [5]. Persons sustaining upper limb amputations present complex rehabilitative needs that are ideally best managed by a rehabilitation center with therapists, prosthetists, and physicians possessing specialized knowledge and experience. Proper rehabilitation and a comfortable and functional prosthesis will facilitate functional restoration. Vocational counseling and vocational retraining are vital aspects of any program as this condition often afflicts young, vocationally productive persons, primarily men. A continuum of care is vital to successful rehabilitation. Patients must be transitioned effectively from the inpatient postsurgical unit, sometimes to an inpatient rehabilitation unit and always to a long-term outpatient rehabilitation and prosthetic program.

Symptoms

Congenital upper limb amputees may report no specific symptoms except the lack of full upper extremity function. In contrast, traumatic upper limb amputees may describe phantom pain (pain perceived in the missing part of the limb) or phantom sensation (nonpainful perceptions of the missing part of the limb). Discomfort with prosthetic fit or skin breakdown on the residual limb may be reported in prosthetic users.

Physical Examination

Upper limb amputees require a thorough musculoskeletal examination that includes muscle strength testing, sensory testing, and examination of the contralateral limb. Examination of the residual limb should assess for areas of skin breakdown, redness, painful neuroma, and volume changes that could affect prosthetic fit. Persons with traumatic amputations of the upper limb can have brachial plexus injuries or rotator cuff tears that weaken the residual upper limb muscles. Insensate skin can predispose a patient to breakdown at the site of contact with a prosthesis. Joint range of motion should be assessed. In particular, the scapulothoracic motion is important as protraction of the scapulae provides the force for a dual-control cable system for body-powered prostheses. Reduced elbow or shoulder range of motion from heterotopic ossification, joint capsule contracture, or muscle contracture can impede maximum recovery of function or use of a prosthesis.

Functional Limitations

An upper limb amputee's functional status depends on the level of amputation. Persons with finger loss (not including the thumb) are quite functional without a prosthesis. Persons with thumb amputations lose the ability to grip large objects as well as fine motor skills that require opposition with another finger. Reconstructive surgery by pollicization with another remaining finger dramatically improves hand function.

Transradial and transhumeral amputees lose hand function and have limitations in basic and higher level activities of daily living, such as dressing. Jang and colleagues [11] surveyed upper extremity amputees regarding the impact on activities of daily living. Subjects reported difficulty with complex tasks and either changed jobs or became unemployed. The most common difficulties in daily living were lacing shoes, using scissors, and removing bottle tops [11]. Upper limb amputees frequently sustain new vocational limitations that can preclude return to their previous work activities. Most persons can adapt to almost all basic daily activities with use of the intact contralateral hand and upper limb.

Prosthetic devices may or may not improve function. Some amputees find upper limb prosthetic devices cumbersome, discarding their use altogether. Datta and colleagues [12] found a 73.2% return to work rate after upper limb amputation, although 66.6% had to change jobs. The overall rejection rate of the prosthesis in this study population of predominantly traumatic upper limb amputees was about 34%. The vast majority used the prosthesis

primarily for cosmesis; 25% of patients reported that the prosthesis was beneficial for driving, and a small proportion used it for employment and recreational activities. Some amputees require a specialized prosthesis to continue their specific work-related activities. Recreational activities such as golf, tennis, and other sports can often be accomplished with the use of adaptive prosthetic devices designed for these specific purposes. Return after amputation to such enjoyable pursuits can be quite therapeutic.

Diagnostic Testing

No special diagnostic testing is generally required beyond a careful physical examination. If there is weakness of the limb, electrodiagnostic testing may clarify whether a plexopathy is also present. Radiographs may be necessary to evaluate for osteomyelitis, heterotopic ossification, or a bone spur in the distal limb causing poor prosthetic fit. If myoelectric prostheses are considered, electromyographic signals and voluntary control of key muscles can be tested by a specialized therapist to determine if such control is possible and to train the amputee to independently use these potential control muscles.

Treatment

Initial

Management of persons with upper limb amputations involves a continuum of care [3,10,13–16]. This begins with provision of preoperative information when the amputation is elective, as in the case of cancer. The overriding concern in planning the amputation is to save all possible length, particularly the elbow joint. This preserves elbow flexion and prevents the need for a dual-control cable system. The early input of a physiatrist, nurse, and physical or occupational therapist with expertise in this area is highly advantageous. Early involvement of the rehabilitation team can provide helpful information about prosthetic options, the rehabilitation continuum, and what can be expected after amputation (such as phantom sensations).

Rehabilitation

Initial Rehabilitation Care

Immediately after amputation, the primary goals are wound healing, edema control, and prevention of contractures and deconditioning. Persons sustaining upper limb amputations due to trauma or cancer generally have normal underlying blood supply, and most surgical sites can readily heal. Edema is prevented by use of a shrinker sock, elastic bandage wrapping with a figure-of-eight technique that provides pressure distally without choking the limb, or a rigid dressing system. In sophisticated centers, immediate postoperative prosthesis fitting in the operating room is implemented. The immediate postoperative prosthesis is placed over the limb after padding of the skin with soft dressings. The immediate postoperative prosthesis accommodates surgical drains yet prevents the formation of edema. Prosthetic components can be attached to the immediate postoperative prosthesis and early training implemented.

Postoperative early identification and treatment of adherent scar tissue are important. Scar can form between skin, muscle, and bone. These adhesions can cause pain when muscles are contracted or a joint is moved during operation of the prosthesis [17].

Residual limb pain and phantom pain are two conditions that can affect patients with upper limb amputations [14]. Phantom sensations are common; yet fortunately, disabling phantom pain occurs in only about 5% of amputees [13]. Despite the many interventions used for phantom pain, there are no uniformly effective treatments [13,15]. Medication and physical modalities must be tried in a rational fashion to determine the most effective intervention. Physical modalities include a transcutaneous electrical nerve stimulation unit, physical manipulation, and massage of the residual limb [13]. Fitting of a comfortable prosthesis can often help reduce these painful sensations.

Neuromodulating medications, such as tricyclic antidepressants and antiepileptics (gabapentin and pregabalin), are frequently used with variable results [13,15]. Beta blockers (propranolol and atenolol) have been found to be somewhat effective in treating phantom pain [13]. If patients require cardiac or hypertension medications, the choice of a beta blocker may serve two purposes for these amputees with phantom pain.

Opiates may be effective for these problems when other methods fail to relieve phantom pain [15]. If it is anticipated that the person with phantom pain will need analgesia for a long period, long-acting opiates should be used. Longer acting opiates have less habituation and addiction potential. Most amputees with phantom pain have intermittent severe pain that can be treated with small doses on an as-needed basis of a short-acting opiate, such as oxycodone. For the few patients with severe, unremitting, phantom and residual limb pain, referral to a specialized pain center is suggested.

Rehabilitative and Prosthetic Management

Prevention of contractures in the residual limb and prevention of generalized deconditioning are important goals of early rehabilitation. Any other injuries, as are common in persons sustaining severe trauma, should be identified and rehabilitation efforts directed at their remediation. For body-powered prostheses, scapulothoracic motion provides power through a cable system to operate the prosthesis. Therefore, to optimize function, therapeutic exercise to optimize shoulder range of motion and scapular stabilization is important. Likewise, elbow contractures or shoulder contractures or capsulitis will severely impede maximal prosthetic use, and these problems should be aggressively addressed. Early training in activity of daily living skills should be pursued as well. Therapies should be directed toward amelioration of weakness through exercises or of contractures through active-assisted range of motion exercises and prolonged stretching.

A detailed discussion of prosthetic devices is beyond the scope of this chapter, and consultation with a skilled prosthetist and physiatrist is desirable. Prostheses can serve a cosmetic (passive) role or a functional role, or both [18]. In general, there are two types, body-powered and myoelectric devices [3,16,18]. Body-powered prostheses enable an amputee to harness residual body movements to generate controlled movement and force of a terminal

device [18]. Body-powered devices are usually less cosmetic and associated with limited range of motion and limited prehensile strength, yet they are less expensive and much more durable [18]. Myoelectric prostheses are controlled by electrical signals generated in muscles from the remaining residual limb or shoulder girdle. Myoelectric prosthetic devices extract signals from remaining muscles under voluntary control to activate and to control drive motors in the prosthesis [19]. These devices are expensive, and special prosthetic skills are required to fabricate and to maintain them, but they are generally more cosmetic in appearance and well suited for selected patients. Prosthetic functional outcomes depend on an individual's goals related to cosmesis, function, and psychological factors [17]. Prosthetic prescription should also consider an individual's level of cognitive functioning and ability to learn to operate a device. Skin breakdown can occur over bone prominences, where there are skin grafts, or where skin is adherent to underlying bone. Alteration of the prosthetic socket and suspension systems or temporary discontinuation of prosthetic use until the skin has healed may be necessary.

To meet the needs of military amputees, the Defense Advanced Research Projects Agency (DARPA) has funded development of two advanced upper limb prosthetic solutions. One of the technologies uses neural control; the other, DEKA arm, uses a "strap and go" system that can be controlled by noninvasive means [5]. Implementation of advanced technology requires a coordinated approach using multiple members of the rehabilitation team. Success is largely contingent on the availability of highly trained and specialized personnel to fit and train amputees and resources to pay for these services [5]. Telemedicine may help overcome some of these barriers. The field of upper extremity prosthetics is changing with the development of implantable neurologic sensing devices and targeted muscle innervation. Targeted motor reinnervation incorporates the transfer of residual peripheral nerves into muscles in or near the residual limb, with subsequent reinnervation of those muscles. By use of these surface electromyographic signals that relate directly to the original function of the limb, control of the externally powered prosthesis occurs [20]. Multidextrous terminal devices may soon be available [17].

Procedures

Most procedures related to the care of upper extremity amputees focus on pain management techniques, such as injection of local anesthetic around a painful neuroma, nerve blocks, massage, or chiropractic manipulation. Acupuncture, hypnosis, and biofeedback have also been used in the management of phantom limb pain with variable success [15].

Surgery

Revision surgeries are sometimes necessary to remove bone spurs that interfere with prosthetic fitting. The initial surgery should spare all length possible, particularly the elbow joint. A well-healed surgical site with good distal soft tissue coverage of the bone end is an optimal result that facilitates prosthetic use. In addition, surgical treatment of adherent scar tissue may be necessary to improve function of

a prosthesis. In a study of combat-related upper extremity amputations, 42% underwent revision surgery. The most common indications for revision surgery, in order of decreasing frequency, are heterotopic ossification excision, wound infection, neuroma excision, wound dehiscence, scar revision, and contracture release. In the group that underwent revision surgery, regular prosthesis use increased from 19% before the revision to 87% after it [21].

Potential Disease Complications

As a result of the upper limb amputation, residual limb pain, including severe phantom pain, can occur. Joint contractures can develop in the remaining part of the limb, as can frozen shoulder and adhesive capsulitis. This is a particular concern with coexistent peripheral nerve or brachial plexus injury. Self-reported musculoskeletal pain is more frequent in upper limb amputees than in controls, frequently located in the neck, upper back, and shoulder region [22].

Depression brought on by the difficulties of adjusting to limb loss is reported. Psychological counseling and support groups incorporating peer support are valuable resources.

Potential Treatment Complications

Surgical complications include postoperative wound infections and postoperative failure of the surgical wounds to heal. Neuroma formation can occur after transection of a nerve. Burying the nerve ending under large soft tissue masses may reduce the likelihood of neuroma irritation.

Many medications used in the treatment of phantom pain associated with amputations have potential side effects, including dry mouth, constipation, weight gain, mental cloudiness, cardiovascular effects, and addiction. The side effect profiles vary by the medication class and dosage.

Skin breakdown from a poorly fitting prosthesis can occur. This can be aggravated by hyperhidrosis, folliculitis, or poor hygiene.

Overuse injuries in the nonamputated limb reportedly are higher than expected in the normal population [12]. These include repetitive strain-type injuries due to the individual's performing certain tasks with poor body posture and ergonomics [23].

Z89.619 Acquired absence of unspecified leg above knee

Definition

In 2005, an estimated 1.6 million persons in the United States were living with loss of a limb, of whom 65% have had a lower limb amputation [1]. Vascular conditions account for most cases of amputation (54%), with two thirds of these having a secondary diagnosis of diabetes [2]. Lower limb amputations account for 97% of all dysvascular amputations. More than half of dysvascular amputations are major lower limb amputations (transfemoral, 25.8%; transtibial, 27.6%) [2,3]; 42.8% involve other levels (ray, toes). Most of these amputations occur in people aged 60 years and older. There are approximately 82,000 nontraumatic diabetes-related lower extremity amputations each year [3]. Trauma is the next most common cause of lower extremity amputation (22%), followed by tumors (5%). However, in children aged 10 to 20 years, tumor is the most common cause of both upper and lower extremity amputations. Male amputees outnumber female amputees 2.1:1 in disease and 7.2:1 in trauma [4]. Across all causes, 42% of the persons living with the loss of a limb are 65 years or older; 65% are men, and 42% are nonwhite [2].

Symptoms

The postoperative or post-traumatic sequela of an amputation is that the patient is missing all or part of a limb. In addition, there may be associated symptoms, such as phantom limb sensation, phantom pain, stump pain, and pain from the surgery itself.

Phantom limb sensation is the perception that the extremity is still present and occasionally distorted in position. Phantom limb sensation typically fades away within the first year after amputation, usually in a “telescoping” phenomenon. This includes the perception that the distal aspect of the limb (that is, the foot) is moving closer and closer to the site of amputation.

Phantom limb pain is differentiated as a painful perception within the absent body part. The incidence of phantom limb pain is variable and has been reported from 0.5% to virtually 100% of persons with amputations. This variability is due to differences in study methods and population. The most recent studies suggest that up to 85% of people with amputations will experience phantom pain [5]. Patients may describe the pain in the absent foot or the absent limb as cramping, stabbing, burning, or icy cold.

Pain at the surgical site is common and should resolve within a few weeks of surgery. Residual limb pain is perceived in the residual limb in the region of the amputation. The incidence of residual limb pain has been reported between 10% and 25%; it may be diffuse or focal and is commonly associated with neuroma, which is palpable around the amputation site.

Physical Examination

Wound healing, range of motion, muscle strength, and incisional integrity must be evaluated in the residual limb. Upper extremity strength should be assessed to determine capability for use of assistive devices.

Visualization of the contralateral foot is a mandatory component of the examination. The unaffected foot is assessed for areas of potential breakdown. These include the plantar surface of the foot, web spaces, and areas of bone prominence.

Skin breakdown in the residual limb is typically a result of pressure or shear forces in the healed limb. Skin necrosis may be evidence of ischemia with need for surgical revision. Skin breakdown can be manifested as abrasions from tape or the unraveling of an elastic wrap or be true partial- or full-thickness (pressure) sores. Pressure sore phenomenon typically occurs at bone prominences. The fibular head, hamstring tendons, patellar tendon, medial and lateral femoral condyles, and anterior distal tibia should routinely be examined for skin breakdown.

Joint contractures are a loss of full range of motion at a joint. They may be conceptualized as functional or mechanical. Functional contractures are the result of (inappropriate) positioning. A transtibial amputee may develop knee or hip flexion contractures merely by sitting with the hip flexed and the knee flexed at 90 degrees (the knee and hip extensors remain intact but are not being used). A mechanical contracture may result from unopposed muscle action. In the transfemoral amputee, the insertion of the hip adductors is sacrificed and the unopposed (and firmly attached) hip abductors may result in an abduction contracture.

The transtibial and Syme amputee requires evaluation of range of motion of the knee in flexion and extension. Medial and lateral knee stability must also be assessed. For successful ambulation with a prosthesis, knee extension muscle strength should be graded at least higher than 4/5.

A knee flexion contracture of 10 degrees up to 18 degrees can usually be accommodated in a transtibial prosthesis; however, the absence of limb contractures is related to better success in prosthetic ambulation [6]. A contracture of more than 20 degrees requires that the individual ambulate with a bent socket, weight bearing through the knee.

In the transfemoral (above-knee) amputee, the range of motion evaluation should include hip flexion, hip extension, hip adduction, and hip abduction. A transfemoral prosthesis can functionally accommodate up to a 20-degree hip flexion contracture; a contracture of more than this makes prosthetic fitting and successful ambulation less likely. Strength should also be assessed, and grades of 4/5 or higher in muscles responsible for hip flexion-extension and abduction are required for ambulation.

Stump or residual limb pain is assessed first by inspection. Areas of obvious necrosis indicating poor blood flow may require surgical débridement. Nonhealing incisions are manifestations of ischemia, underlying hematoma, or abscess. The surrounding area should be palpated and assessed for induration and discharge. An attempt should be made to “milk” fluctuance, and drainage should be sent for Gram stain and culture. Sutures (if present) may need to be removed to facilitate evacuation of the abscess or hematoma. In some instances, the incision may need to be reopened for drainage and healing to take place.

Stump pain without signs or symptoms of infection should be evaluated for neuroma (palpation along the anatomic course of the sciatic nerve). Stump pain with or without skin breakdown may also be due to poor prosthetic fit, so the fit of the prosthesis ought to be evaluated, preferably with a prosthetist present. Nonblanchable erythema is a pressure sore until proved otherwise, and the prosthesis should not be worn until appropriate adjustments are made. Bruising at the distal aspect of the stump in the prosthetic wearer is indicative of a poor prosthetic fit. That is, the residual limb may be falling too deeply into the socket. Similarly, a choke phenomenon occurs with lack of total contact or inability to get the residual limb all the way into the socket. This can progress to verrucous hyperplasia, which predisposes the individual to fissuring and infection.

Gait evaluation with the prosthesis should be performed with an appropriate assistive device. Observed gait deviations should be communicated to the prosthetist for prosthesis modifications and to the therapist for focused gait training.

Functional Limitations

Functional limitations are largely dependent on the premorbid status of the individual. Ambulation with one limb or hopping (with a walker or crutches) requires approximately 60% increased energy over normal human locomotion. The energy cost of ambulation with a prosthesis varies. In the diabetic or dysvascular amputee, it approaches 38% to 60% increased energy for a below-knee amputee and 52% to 116% higher for an above-knee amputee [2,6]. An otherwise healthy person who has sustained a traumatic limb amputation or an individual who had been ambulating with crutches or another assistive device before having an amputation (often because of non-weight-bearing status

on the affected limb) will probably be discharged from the acute care setting to home with outpatient services, at an “ambulatory” level with the appropriate assistive device; the energy expenditure will be less than that of a dysvascular amputee.

An older individual or person with multiple comorbidities should be encouraged to pursue functional independence by optimizing wheelchair mobility and transfers when there is inadequate cardiopulmonary reserve to ambulate with an assistive device [7]. This person may have had an acute or subacute rehabilitation hospital stay after the acute care hospitalization.

Functional limitations due to pain are associated with an inability to participate in ongoing activities of daily living. In general, symptoms of phantom sensation tend not to be an issue, whereas phantom pain can be severely limiting, preventing a person from participating in pre-prosthetic and prosthetic rehabilitation. Functional limitations related to stump or residual limb pain include the inability to tolerate stump shrinkage by appropriate modalities and an inability to tolerate gait training with a prosthesis. To accommodate stump pain, the patient may develop gait deviations to decrease pressure under the residual limb.

Individuals with significantly impaired cardiac output may not be able to perform pre-prosthetic training with a walker (or crutches). These patients may not be prosthetic candidates at all because of the increased energy demands of prosthetic ambulation [6]. Coronary artery calcification scores were very high in amputees compared with Framingham Risk Score-matched control groups. This suggested moderate to extensive coronary artery disease in more than two thirds of amputees studied. It may be relevant to carefully evaluate amputees for asymptomatic coronary artery disease and to consider prophylactic revascularization [8]. Keep in mind that individuals with preexisting amputations who undergo coronary artery bypass grafting will not be able to use an assistive device postoperatively (maintenance of sternal precautions), and alternative mobility options (e.g., power wheelchair) should be considered.

Rates of clinical depression range from 18% to 35% among amputees. Those with amputation-related pain are more prone to depression. Depression should be differentiated from the grief response and postoperative adjustment period [9].

Diagnostic Studies

The individual with phantom limb pain may benefit from diagnostic as well as therapeutic sympathetic nerve block. On occasion, electrodiagnostic tests (electromyography and nerve conduction studies) are helpful to differentiate symptoms of radiculopathy or other disease in the phantom limb.

In the younger amputee, it is occasionally necessary to obtain plain radiographs of the residual limb to assess the bone overgrowth. This is typically visually evident on inspection; the radiograph confirms the extent of overgrowth.

The individual with new amputation secondary to peripheral vascular disease may require cardiac evaluation to establish parameters for an exercise prescription.

Differential Diagnosis

Secondary conditions related to residual limb

- Edema
- Neuroma
- Incision
 - Postsurgical
 - Infection
- Bone overgrowth
- Ischemia
- Phantom pain
- Sympathetic pain
- Radiculopathy
- Ischemia

Treatment

Initial

Initial treatment focuses on edema control and shaping of the residual limb as well as wound healing, prevention of contractures, and pain management. Options for edema control are listed in Table 119.1 [10,11].

Patients with a transtibial amputation have the potential for knee flexion and hip flexion contractures as a result of positioning (usually, sitting in a wheelchair or in bed). Therefore, avoidance of pillows under the knee and promotion of lying prone in bed can be helpful.

Persons with a transfemoral amputation may also develop hip flexion contractures as a result of sitting. In addition, there is the tendency for development of hip abduction contractures, so positioning of the hip in relative adduction, avoidance of pillows under the residual limb, and promotion of the prone position are essential.

Phantom sensation is not typically painful, although it can be frightening or disorienting for the patient. The best treatment is to reassure the patient that this is a normal reaction after amputation. Education and reassurance of the patient as well as ongoing tactile input (i.e., massaging the distal residual limb and using the limb) will enhance the accommodation to phantom sensation. There are many proposed treatments of phantom pain; however, there is no one definitive treatment that seems to work best. Initial pharmacologic intervention includes non-narcotic and narcotic analgesics; nonsteroidal anti-inflammatory drugs; anticonvulsants and membrane stabilizers, particularly gabapentin, duloxetine, and pregabalin; and tricyclic antidepressants [9].

Rehabilitation

Pre-prosthetic training focuses on functional independence in mobility and self-care from the ambulatory (single limb) or wheelchair level, avoidance of hip and knee contractures, and residual limb management. Prosthetic training is initiated once the residual limb is ready—the edema is resolved and the incision has healed; the prosthesis is then fabricated. A description of prostheses is beyond the scope of this chapter; however, the reader is referred to one of several texts on prosthetic components and prescription [12,13]. K levels are used by Medicare to determine an individual's functional potential and thus to justify prosthetic

Table 119.1 Treatment Options for Edema Control

Treatment Options	Advantages	Disadvantages
In a Below-Knee Amputee		
Above-knee cast	Prevents knee flexion contracture Provides protection No patient “skill” or management necessary to remove Very low cost	Bulky, awkward, heavy to move Unable to visualize wound Unable to remove Potential for skin breakdown
“Stump shrinker”	Easy to don and doff Enables visualization of wound Accustoms individual to use of a sock Provides shaping of residual limb	Cost—may need to be replaced after stump has begun to shrink
Rigid removable dressing (Fig. 119.1)	Excellent for preparing residual limb for eventual prosthesis Fosters patient’s independence in assessing need for stump socks Good edema management Provides some soft tissue protection Able to view wound	Therapist, physician, and prosthetist must be skilled in fabrication Potential for skin breakdown if applied incorrectly
Elastic bandage (ACE wrap)	Easily available Able to visualize wound Accommodates all shapes and sizes Good edema control	Requires excellent dexterity for patient to don and doff Potential for shear injury if wrap unravels Must be reapplied multiple times a day secondary to potential loosening
In an Above-Knee Amputee		
Stump shrinker, elastic bandage	Same advantages and disadvantages as described for below-knee amputee	

Table 119.2 K Levels

K0 (level 0)	Does not have the ability or potential to ambulate or to transfer safely with or without assistance, and a prosthesis does not enhance the quality of life or mobility
K1 (level 1)	Has the ability or potential to use a prosthesis for transfers or ambulation on level surfaces at fixed cadence—typical of the limited and unlimited household walker
K2 (level 2)	Has the ability or potential for ambulation with the ability to traverse low-level environmental barriers, such as curbs, stairs, or uneven surfaces—typical of the limited community walker
K3 (level 3)	Has the ability or potential for walking with variable cadence—typical of the community walker who is able to traverse most environmental barriers and may have vocational, therapeutic, or exercise activity that demands prosthetic use beyond simple walking
K4 (level 4)	Has the ability or potential for prosthetic use that exceeds basic walking skills, exhibiting high impact, stress, or energy levels—typical of the prosthetic demands of the child, active adult, or athlete

components (Table 119.2). When the prosthesis has been fabricated, an outpatient appointment with the ordering physician is scheduled that is attended by the patient and the prosthetist. A basic evaluation of the fit of the prosthesis is conducted, and referral for physical therapy that focuses on prosthetic training is made at that time, or adjustments to the prosthesis are made. The patient must be taught how to put on (don) and take off (doff) the prosthesis as well as when to add socks for a better fit. The patient should also be encouraged to routinely inspect the skin on the residual limb (often done best with a long-handled mirror).

FIGURE 119.1 Application of the removable rigid dressing. (From Lennard TA. *Pain Procedures in Clinical Practice*, 2nd ed. Philadelphia, Hanley & Belfus, 2000.)

Occupational therapy consists of identifying necessary equipment (e.g., toilet safety frame, tub transfer bench) and establishing independence in self-care from the wheelchair or ambulatory level with use of just the unaffected limb (single-limb stance). Occupational therapy should also be ordered when the patient receives the prosthesis to establish independence in self-care, particularly with lower extremity dressing, toileting, and homemaking while the prosthesis is worn.

Return to driving is an important aspect of functional independence. The majority (80.5%) of prosthetic users with major lower extremity amputations are able to return to automobile driving 3.8 months after amputation. People with left-sided amputations have significantly fewer concerns about driving; those with right-sided amputations may need vehicle modifications (40%) or may need to switch to left-foot driving style [14].

Procedures

Treatment of postamputation phantom pain includes sympathetic blocks, which are typically performed under fluoroscopic guidance. Neuromas, which typically form 1 to 12 months after amputation, may be manifested as a focal soft tissue mass with reproducible pain on palpation. Local anesthetic injection may provide pain relief. Surgical resection is an option but can result in a new (painful) neuroma [15].

Surgery

Surgery is indicated when a residual limb requires wound revision or higher level of amputation. Hamstring releases have a limited role or no role because they would inhibit the ability to walk. There does not appear to be any role for surgical stump revision for treatment of phantom pain.

There are few data to promote dorsal root entry zone ablation, dorsal rhizotomy, dorsal column tractotomy, thalamotomy, or cortical resection in the treatment of phantom pain. A small trial to surgically treat phantom pain locally was performed. The sciatic nerve was split proximal to the popliteal fossa, and the two parts were reconnected in a sling fashion. Of 15 patients, 14 reported that the procedure was “very helpful.” [15]

Bone overgrowth develops in 10% to 30% of children with congenital amputations, and this must be addressed surgically. This is much less common in the adult with an acquired amputation.

Potential Disease Complications

The most common complications are dehiscence or breakdown of the incision and nonhealing wounds. Infection or ischemia is the most likely cause of dehiscence or a nonhealing incision. A trial of conservative management including antibiotics (after a culture specimen is obtained) and appropriate local wound care is reasonable. Increasing wound necrosis, foul drainage, and fever or chills warrant reevaluation by the surgeon.

Other potential complications may involve cardiac ischemia as a heretofore inactive (i.e., energy conservative) individual begins using up to 100% more energy for gait training [6]. A reasonable guideline for gait training is assessment of an individual's ability to ambulate with the intact lower extremity with crutches or another assistive device. This consumes approximately 60% more energy than bipedal human locomotion. A person who is not able to gait train (hop on one foot short distances) with use of an assistive device is probably not a potential prosthetic ambulator. Major limb amputation continues to result in significant

morbidity and mortality. One-year survival for dysvascular and diabetic individuals is 50.6% for transfemoral amputees and 74.5% for transtibial amputees. Five-year survival is 22.5% and 37.8% (survival in end-stage renal disease is as low as 14% at 5 years after amputation) [2,3].

Potential Treatment Complications

Once the prosthesis has been fabricated, skin breakdown is the most common complication. Breakdown commonly occurs at the distal anterior tibia (clapper-in-bell phenomenon, a result of continued forward motion of the distal residual limb in the socket during swing phase), the hamstring tendons (tight brim), and the patellar tendon.

Patients should be instructed to inspect these areas and immediately report to the prosthetist signs of persistent, nonblanchable erythema. The prosthesis should not be worn until modifications are made.

Medication side effects depend on the particular medication being used as well as potential for drug interactions when multiple medications are being used.

M45.7 Ankylosing spondylitis of lumbosacral region
M45.8 Ankylosing spondylitis of sacral and sacrococcygeal region
M45.9 Ankylosing spondylitis of unspecified sites in spine

Definition

Ankylosing spondylitis is a chronic, inflammatory, rheumatologic disorder that primarily affects the spinal column and sacroiliac joints. It is classified as a seronegative

spondyloarthropathy. Enthesitis (inflammation of the soft tissues attaching tendons, ligaments, and joint capsules to bone), synovitis, and inflammation of the synovial capsule are characteristic of its involvement. The most common sites include sacroiliac, apophyseal, and discovertebral joints of the spine; costochondral and manubriosternal joints; paravertebral ligaments; and attachments of the Achilles tendon and plantar fascia. Peripheral joint involvement is less common but occurs in the more severe forms of the disease or with younger age at onset [1].

The onset of symptoms is usually in late adolescence or early adulthood, and there is a 3:1 male predilection. It is not associated with the presence of rheumatoid factor or antinuclear antibodies. Although there is a genetic association with the HLA-B27 histocompatibility antigen (approximately 90% of ankylosing spondylitis patients express the HLA-B27 genotype), this antigen has not proved to be an adequate screening marker as only 5% of individuals with the HLA-B27 genotype contract the disease. Thus, HLA-B27 is not necessary to confirm the diagnosis [2].

Symptoms

Inflammatory spondyloarthropathies should be considered in any young adult patient who complains of insidious onset, progressively worsening, dull, thoracolumbar or lumbosacral back pain. Other characteristics that should raise suspicion for inflammatory-mediated axial disease include back pain that improves with exercise, shows no improvement with rest, and is responsive to nonsteroidal anti-inflammatory medications and pain at night [3].

Ankylosing spondylitis can have a variable presentation, but sacroiliac pain is a common complaint along with progressive morning stiffness and prolonged stiffness after inactivity. Tendon and ligament attachment sites may become painful and swollen, and one third of patients may have hip or shoulder pain. Chest pain with deep breathing and eye pain with blurred vision, floaters, and photophobia are late symptoms of more severe disease [4]. Neurologic symptoms, such as paresthesias and motor weakness, are usually absent.

Physical Examination

The most typical findings on physical examination are signs of decreased spine mobility and pain at sites of ligament

Note: The opinions in this article are those of the author and not necessarily those of the U.S. Army or Department of Defense.

and tendon attachments. Tests of spinal mobility include the modified Schober test, finger to floor distance, cervical rotation, occiput to wall distance, and chest expansion. The modified Schober test is performed with the patient initially standing in erect position. The examiner identifies the posterosuperior iliac crest line (i.e., lumbosacral junction) and makes two midline marks, one 10 cm above the iliac crest line and one 5 cm below the iliac crest line. The patient is then instructed to perform forward trunk flexion while the examiner measures the distance between the two marks. Normal spinal mobility is indicated by an increase of more than 5 cm or a total distance of more than 20 cm; an increase of less than this would suggest limited lumbar spine mobility. The inability to touch the occiput to the wall while standing against it and the inability to expand the chest by more than 3 cm in full inhalation are late findings in the disease [5].

On palpation of the spine, the lower paraspinal muscles and sacroiliac joints may be tender. A Gaenslen test result

may also be positive (Fig. 120.1). Palpation of extremities demonstrates pain at attachment sites of ligaments and tendon (enthesitis), particularly around the heel (e.g., calcaneal enthesitis) and knee (i.e., tibial tuberosity). Peripheral joint swelling and pain with decreased range of motion can be seen in 25% to 30% of patients. A discolored and edematous iris with circumferential corneal congestion occurs in iritis and anterior uveitis. The neurologic evaluation is typically normal with regard to motor, sensory, and reflex examination findings. Weakness may be noted, but it is usually associated with pain, loss of mobility, or disuse.

Functional Limitations

The functional limitations of the patient with ankylosing spondylitis are typically related to spine pain and immobility. The three best predictors of decreased spinal mobility are cervical rotation, modified Schober test, and finger to floor distance, although these measurements have not correlated

FIGURE 120.1 Gaenslen test. **A**, With the patient in side-lying position, the clinician extends the test leg. **B**, With the patient supine, the test leg is extended over the edge of the table. Pain in the sacroiliac joints indicates a positive test result.

with the patient's assessment of disease activity [5,6]. Early in the disease process, decreased spine range of motion is secondary to back pain and muscle spasms. Most dysfunction is mild and self-limited, typically improving with treatment. In severe disease, positioning from hip flexion contractures, thoracic kyphosis, and loss of cervical rotation decrease patients' ability to view activities in front of them and side to side. The most commonly reported activity limitations are interrupted sleeping, turning the head while driving, carrying groceries, and having energy for social activities [7]. Limitations in chest wall motion lead to a reliance on diaphragmatic breathing and a secondary drop in aerobic capacity. Pain, posture, and functional impairments can also significantly affect sexual relationships [8].

The Bath Ankylosing Spondylitis Functional Index and the Dougados Functional Index are functional assessment tools used by clinicians specializing in the care of patients with ankylosing spondylitis that provide a measure of daily function [9–11]. Past studies have shown that approximately 90% of patients with ankylosing spondylitis remain employed, although recent evidence suggests that up to one third of patients experience some form of employment disruption because of pain and physical limitations [4,6,12].

Diagnostic Studies

There is a well-documented lag time between initial onset of symptoms and diagnosis that ranges from 7 to 11 years [13]. Given the lack of specific signs and symptoms for early ankylosing spondylitis, a high level of suspicion is required in young patients presenting with back pain. Laboratory investigation should include inflammatory markers: erythrocyte sedimentation rate and C-reactive protein [11]. Although neither is required for diagnosis and approximately 40% of patients will have normal values, the elevation of acute phase reactants can indicate severity, responsiveness to treatment, peripheral joint involvement, or extra-articular disease. HLA-B27 is present in 90% of patients with ankylosing spondylitis. A negative test result suggests milder disease with a better prognosis. Rheumatoid factor and antinuclear antibodies are absent.

Radiography of the spine and pelvis is the standard imaging modality in diagnosis and assessment of disease, although computed tomography and magnetic resonance imaging are more sensitive for detection of bone changes, especially early in the disease course and particularly in the assessment of the sacroiliac joints [14]. Spine radiographs show ossification of spinal ligaments and apophyseal joints, sclerosis, and syndesmophytes with eventual ankylosis that leads to the classic bamboo spine appearance. Pelvic (sacroiliac and hip) radiographs demonstrate symmetric involvement of the sacroiliac joints with bone erosions, sclerosis, and blurring of the subchondral bone plate eventually progressing to complete ankylosis. On the basis of the modified New York criteria for ankylosing spondylitis, radiographic features of moderate bilateral sacroiliitis or moderate to severe unilateral sacroiliitis plus one clinical feature are required for definite diagnosis of ankylosing spondylitis. Additional radiographic findings include bone erosions at entheses, symmetric and concentric joint narrowing, and subchondral sclerosis of the hip joints with ankylosis in severe disease. Once initial radiographs are

abnormal, further radiographic progression correlates with worsening results of the modified Schober test, although it is recommended that assessment of spinal mobility be used as a proxy for radiographic evaluation [15].

Early computed tomography imaging findings demonstrate pseudowidening of the sacroiliac joints followed by sclerosis, narrowing, and ankylosis. Magnetic resonance imaging can show similar findings but also provides the additional benefit of revealing active inflammation. Sonography can be used to diagnose enthesitis and can also be particularly useful to guide therapeutic interventions and to follow disease progression [16,17].

Differential Diagnosis

- Rheumatoid arthritis
- Other seronegative spondyloarthropathies
- Reiter syndrome
- Psoriatic arthritis
- Enteropathic spondylitis
- Behçet syndrome

Treatment

Initial

Evidence-based treatment guidelines must be tailored to the disease progression and functional impact on the individual with ankylosing spondylitis. The goals of management have been outlined by the European League Against Rheumatism (EULAR) and the Assessment of Spondyloarthritis International Society (ASAS) and should include concurrent medical, rehabilitation, and surgical treatment with the goals of optimizing pain control, maintaining maximal functional capacity with emphasis on spinal range of motion, reducing fatigue, and minimizing impact of extra-axial manifestations [18–20]. Given the variable presentation and progression of symptoms in each patient, an individualized program tailored to the patient's specific needs is necessary.

From a medical standpoint, nonsteroidal anti-inflammatory drugs (NSAIDs) are considered the first-line treatment of patients with ankylosing spondylitis. NSAIDs provide symptomatic relief and have been shown to slow radiographic progression [21–23]. The choice of NSAID is based on individual therapeutic response, compliance, and side effects. Continuous dosing (as opposed to intermittent administration of NSAIDs during periods of exacerbation) is the favored dosing regimen based on the most recent 2010 ASAS/EULAR recommendations; this dosing regimen has been shown to slow structural damage with only marginal increase in side effects [19,22,24].

The recent discovery of biologics has revolutionized the treatment of rheumatologic diseases [25]. Specifically, tumor necrosis factor- α antagonists (infliximab, etanercept, adalimumab, and golimumab) have demonstrated clinical effectiveness in the treatment of ankylosing spondylitis [20]. The choice of tumor necrosis factor- α blocker is based on individual therapeutic response and other factors, such as the presence of extra-axial manifestations or concomitant inflammatory bowel disease. Other disease-modifying agents have shown limited efficacy and are not

generally recommended in the treatment of ankylosing spondylitis with the exception of sulfasalazine, which can be used in cases with a predominance of peripheral disease, inflammatory bowel disease, or psoriasis [20,26]. Pulsed methylprednisolone may be effective for NSAID-resistant flares, although long-term use is not generally recommended because of concern for osteoporosis [19,27]. Pamidronate, when it is used to treat associated osteoporosis, may also decrease ankylosing spondylitis disease progression [28].

Rehabilitation

The benefits of exercise for patients with ankylosing spondylitis are well documented [29]. Individualized programs should include activities to optimize aerobic capacity, flexibility, and pulmonary function [30–32]. Hip range of motion increases with regular stretching with use of the contraction-relaxation-stretching technique. Strengthening of back and hip extensors should follow the flexibility exercises. Aerobic activities may maintain chest expansion. However, an exercise stress test should be considered before an aerobic program if aortic insufficiency is suspected [31].

Despite the well-documented benefits of exercise programs, patients with ankylosing spondylitis are poorly compliant, and not surprisingly, the benefits of these programs are lost once the exercise is discontinued. There is no evidence that a particular type of exercise is superior to another, although specific exercise programs that target strengthening and flexibility of shortened muscle chains show promise [33]. One particular area that has clearly shown benefit is the setting in which the program is performed [19]. A physical therapy supervised group was superior to a home exercise program and both were superior to no intervention for improvements in pain, function, mobility, and patient global assessment. Group exercise also demonstrated improved compliance [29,34,35].

Spa therapy and balneotherapy can be safely recommended and have shown moderate benefit for treatment of pain and improving the patient's assessment of disease activity [36]. Splinting and spinal orthoses are generally not effective. Foot orthotics can help with calcaneal enthesopathies. A firm mattress may help with sleep, along with a small cervical pillow that will help maintain cervical lordosis. Wide mirrors assist drivers with limited cervical mobility [32]. There are no data to support or to refute the use of diet, education, or self-help groups [19].

Procedures

Periarticular corticosteroid injections and fluoroscopically guided sacroiliac joint injections may help during NSAID-resistant flares or when NSAIDs are contraindicated [37]. Local injections for enthesopathies may be effective, but injections in and around the Achilles tendon insertion should be avoided.

Surgery

Hip and knee arthroplasties are effective for patients with intractable pain, limitations in mobility, and poor quality of life. Early referral to an orthopedic surgeon should

be considered as joint replacement is optimal before progression to ankylosis. Age is not considered a limiting factor as young patients have fared well, and long-term studies have demonstrated that more than 50% of patients exceed a 20+-year life span of their prosthesis [38,39]. Spinal osteotomy is an option for patients with severe kyphosis to improve horizontal vision and balance, although there is considerable risk [19,40].

Potential Disease Complications

Potential complications include iritis or uveitis, inflammatory bowel disease, aortic insufficiency, and aortic root dilation [41]. Osteoporosis (best evaluated with bone densitometry of the femur) is common, which increases risk of spine fracture and associated neurologic injury due to relatively minor trauma [42,43]. Recent evidence suggests an increased morbidity and mortality due to cardiovascular disease in patients with ankylosing spondylitis [44].

Potential Treatment Complications

NSAIDs may produce gastrointestinal and renal toxic effects [45]. Corticosteroids increase risk of osteoporosis. Tumor necrosis factor- α antagonists increase the risk of infection, including reactivation of latent tuberculosis. Total hip arthroplasty increases the risk of anterior dislocations. Spinal osteotomy carries the risk of paralysis and a mortality rate of up to 4% [40].

Definition

Repetitive strain injury (RSI) describes nonspecific upper extremity pain that often develops in occupational settings. RSIs are thought to result from the performance of repetitive and forceful hand-intensive tasks. These conditions are also referred to as cumulative trauma disorders, occupational overuse syndromes, and nonspecific work-related upper limb disorders. The varying nomenclature is controversial because it provides little insight into anatomy affected, disease severity, appropriate treatment, or expected prognosis. Classification systems of work-related musculoskeletal disorders often include specific diagnoses, such as carpal tunnel syndrome and de Quervain tenosynovitis, as

RSIs, but the consensus in recent years has been to consider RSI an entirely separate category of occupational disorder [1]. RSIs have symptom complexes that do not fit neatly into another diagnostic classification, such as specific tendinopathy or nerve entrapment. RSIs typically have few objective physical findings and little in the way of demonstrable pathologic change.

RSI is a significant medical concern; approximately 65% of reported cases of occupational illness are attributed to repeated trauma annually [2,3]. In fact, occupational musculoskeletal disorders of the hand and wrist are associated with the longest absences from work and have greater lost productivity and wages than those of other anatomic regions [2]. There is evidence that this condition is actually underreported [4]. Important risk factors appear to be repetitive motion of the arm or wrist, movements that require extremes of hand or arm position, prolonged static postures, and vibration. Other risk factors may be poor ergonomic work environment, task invariability, lack of autonomy, and high levels of psychological distress in the workplace. In addition, the female gender appears to be more susceptible to development of RSI [5]. RSIs can develop outside of the workplace in individuals who participate in hobbies or activities that expose them to repetitive motion and prolonged postures on a consistent basis. A study demonstrated that the adult acquired upper limb amputee population is at increased risk of musculoskeletal pain in the neck/upper back and residual limb as well as in the contralateral remaining arm [6].

According to the U.S. Department of Labor, Bureau of Labor Statistics, occupations that appear to be at greatest risk for RSIs are those in the service and manufacturing industries, including any job involving computer processing and keyboard use [2]. These occupations have the most demand for upper extremity intensive tasks. Because of limitations in the assessment of risk factors, quantitative levels of exposure that are “acceptable” in each occupation are not available [7]. Clinically, it appears that the onset and perpetuation of RSIs are multifactorial. There is no proven etiology of RSI, but it is thought to develop from repetitive microtrauma to muscle, tendon, nerve, loose connective tissue, or bone that exceeds the ability of the tissue to heal itself. In animal models, when chronic repetitive motion is induced, an acute inflammatory response is stimulated in the tissue. This initial response eventually

Table 121.1 Criteria for Referral to a Burn Center**Burn Injuries that Should be Referred to a Burn Center**

Partial-thickness burns greater than 10% of the total body surface area
 Burns that involve the face, hands, feet, genitalia, perineum, or major joints
 Third-degree burns in any age group
 Electrical burns, including lightning injury
 Chemical burns
 Inhalation injury
 Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
 Any patient with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality
 Burned children in hospitals without qualified personnel or equipment for the care of children
 Burn injury in patients who will require special social, emotional, or rehabilitative intervention

From American College of Surgeons, Committee on Trauma. Guidelines for the operation of burn centers. Resources for Optimal Care of the Injured Patient. Chicago, Ill, American College of Surgeons, 2006.

nociceptive pain is a major symptom of burn injury. Involvement of nerve endings in the dermal layer may also result in impaired or altered sensations causing neuropathic pain. Pruritus is common in the acute period and is linked to both the chronic inflammatory state and altered pain pathways of burns. Furthermore, postburn pain and pruritus may persist for years after injury, and regular monitoring with use of standardized measures is recommended. The visual analog scale, numeric pain rating scale, and 5-D scale for itching [5] are useful in assessing symptoms and treatment response.

Deep partial-thickness and full-thickness burns interrupt the function of skin appendages. Damaged skin appendages may include the apocrine sweat glands, resulting in dry, friable skin that does not heal well and is susceptible to infection. In larger burns, the loss of sweat glands may also impair body temperature regulation. The overall poor skin condition after burn injury may lead to chronic wounds.

Scar tissue develops weeks to months after closure of deep partial-thickness and full-thickness burns. Hypertrophic scars and contractures may result. This can be painful, cause deformity, and interfere with joint function. Contractures may lead to subluxation of hand or feet joints and dislocation of hips or shoulders. Scoliosis and kyphosis can result from burn scar contracture and postural changes.

Other symptoms are related to the multitude of other burn complications (see section on potential disease complications), some of which arise from the complex and prolonged intensive care and hospital course. Severe deep injury of extremities can require amputations of nonviable limbs. Formation of osteophytes and heterotopic ossification occur in burns and are associated with long-term immobilization [6]. Chronic infections from skin wounds and immune compromise are significant concerns. Other issues include complications from inhalation injury resulting in chronic pulmonary symptoms, hormone imbalances, deconditioning and malnutrition, and loss of bone and muscle mass [7]. Last, premorbid psychiatric disorders and psychiatric complications from the burn itself are prevalent

and include sleep disturbances, depression, anxiety, substance abuse, and post-traumatic stress.

Physical Examination

A thorough physical examination is necessary to assess the burn itself as well as resulting complications. The evaluation should begin with an examination of the skin for burn location and depth, sensation, and signs of infection. Determination of burn depth allows categorization of wound severity.

The current burn classification system groups burns into four categories of varying depth: superficial, superficial and deep partial thickness, and full thickness. Superficial injuries, traditionally known as first-degree burns, solely affect the epidermal layer. The category of second-degree burns is divided into superficial and deep partial-thickness burns. Superficial partial-thickness burns interrupt the epidermis and superficial (papillary) dermis. These often have good vascular supply and are painful with a pink or red and sometimes blistered appearance [8]. Deep partial-thickness burns extend into the deep (reticular) dermis and damage skin appendages, which affects some degree of sensory and apocrine function. Full-thickness burns, also called third-degree burns, affect the entire epidermal and dermal layers and result in complete loss of skin appendages. Deep partial-thickness and full-thickness burns usually have poor blood flow and can be painless and appear less red [8]. Severe injuries also may penetrate to the muscle, tendon, and bone. Such deep injuries, classified as fourth-degree burns, are not part of the newer anatomic classification system (Fig. 121.1 and Table 121.2).

The depth of burn is an important factor in determining acute management of wounds. Burn surgeons often classify burns as superficial wounds, which heal by conservative management, or deep wounds, which require surgical intervention. Clinical assessment is the most widely used

FIGURE 121.1 Diagram of skin anatomy with subdivisions by degree of burn.

Table 121.2 Burn Severity Classifications

Classic Classification	New Classification	Appearance and Symptoms	Course and Treatment
First degree (epidermis)	Superficial thickness	Erythematous; dry, mildly swollen; blanches with pressure; painful	Exfoliation; heals spontaneously in 1 week; no scarring
Second degree (dermis)	Superficial partial thickness Deep partial thickness	Blistering; moist, weeping; blanches with pressure; painful No blisters; wet or waxy dry; variable color; less painful; at risk for conversion to full thickness because of marginal blood supply	Reepithelialization in 7-20 days Reepithelialization in weeks to months; skin grafting may speed recovery; associated with scarring
Third degree (all of dermis and epidermis)	Full thickness	White waxy to leathery gray to charred black; insensate to pain; does not blanch to pressure	Reepithelialization does not occur; requires skin grafting; associated with scarring
Fourth degree (extends to muscle, bone, tendon)	—	Black (eschar); exposed bones, ligaments, tendons	May require amputation or extensive deep débridement

technique to evaluate burn wound depth and severity. Unfortunately, the clinical evaluation is accurate only about 64% to 76% of the time, and other techniques, briefly discussed in diagnostic studies, may also be used to evaluate wound depth [9,10]. Because of the evolving nature of burn wounds in the first few days after injury, monitoring the progression of the wound over time allows one to best assess its ultimate anatomic classification and management plan.

Postoperative burn wounds should also be closely watched in the rehabilitation setting. Postoperative wound evaluation includes inspection of grafts for hematoma, seroma, infections, and areas of graft loss [8]. After skin grafting, and as the skin matures, one should monitor for signs of hypertrophic scarring, which initially appears as erythematous, raised, and hardened skin.

A complete neurologic examination including an assessment of motor and sensory function, reflexes, and cognition should also be performed. Immediately after injury or surgery, the sensory examination is primarily limited to light touch modality because of pain. However, after wound closure, the sensory examination enables one to evaluate for small- and large-fiber neuropathies. Deep burn wounds may involve the vascular supply and affect wound healing. A pertinent vascular examination includes assessment of peripheral pulses of the involved extremities. The musculoskeletal examination should assess not only strength but also joint range of motion and deformities. The motor examination of joints crossed by a deep partial-thickness or full-thickness burn should not be performed until after skin graft “take” is ensured, usually within a week after grafting. Note that burn patients may have significant weakness from deconditioning and lean muscle loss. A complete cardiac and pulmonary examination should be performed with particular attention to signs of respiratory complications and hypermetabolic state. Psychiatric examination should include a thorough screening for signs of sleep disturbance, depression, anxiety, substance abuse, and post-traumatic stress. Patients who exhibit symptoms of a major psychiatric disorder should receive a complete psychiatric evaluation.

Functional Limitations

Functional limitations are directly related to the severity and location of the burn and related complications. Those

with burns to the upper extremities may experience impairments in activities of daily living, fine motor tasks, and occupational activities. Burns to the lower extremities may result in impairments in mobility and higher level exercise and sport activities. Small burns to sensitive areas such as the face, including the eyes, ears, nose, or mouth, and genitals may result in significant impairments in specific functions.

Another effect is impaired psychological function. Psychological impairments are common and significant, leading to difficulty with community and social integration [11,12]. Factors associated with delayed return to work include increased hospital length of stay, electrical etiology, injury at work, and the need for inpatient rehabilitation. After hospitalization, barriers for returning to work include pain, neurologic issues, and impaired mobility [13].

Diagnostic Studies

Many different diagnostic tests are useful in the initial assessment of the burn patient. These may include tests to assess wound depth. The “gold standard” of burn depth analysis is biopsy with histologic assessment, but this is not standard practice [14]. Techniques using laser Doppler imaging, thermography, vital dyes, ultrasonography, and confocal laser scanning microscopes have been suggested for wound depth assessment, but these methods are not routinely used clinically. Bronchoscopic evaluation of the airway is performed for inhalation injury along with serum carboxyhemoglobin level.

In the rehabilitation setting, diagnostic tests are targeted toward short- and long-term sequelae of burns. Plain radiographs are used to evaluate for abnormal bone and joint changes, such as bone growth deformity in children, osteophytes, or joint subluxation and dislocation. Plain films are also used to evaluate heterotopic ossification but may not demonstrate findings until 3 weeks (see Chapter 130) [15]. Heterotopic ossification is diagnosed as early as 7 days after formation with a triple-phase bone scan. The aberrant ossification is visualized by increased uptake in the third phase of the scan. For patients with signs or symptoms of peripheral nerve injury, nerve conduction study and electromyography are used for the diagnosis of neuropathy.

Differential Diagnosis

Thermal injury
Electrical burns
Chemical burns
Radiation burns
Scalding

Treatment

Initial

The initial management of the severely burned patient focuses on the ABCs: airway, breathing, and circulation. Aggressive fluid resuscitation to compensate for insensible fluid losses is a mainstay of acute management [16], but recent literature has shown overresuscitation to be a possible complicating issue [17]. Other principles of initial management include maintenance of clean and protected wounds, use of antimicrobial agents and infection prevention, emergent relief of ischemic compression by fasciotomy or escharotomy, and early excision and grafting of open wounds. A detailed review of the rapid advances in acute management of burn injuries is beyond the scope of this chapter.

Rehabilitation

Rehabilitation of burn patients is a complex issue. The most common and significant issues are discussed in this section.

Pain

Pain management after burn injury is an integral part of rehabilitation. Background nociceptive pain from the injury itself and exacerbations of pain from therapy, dressing changes, débridement, and other procedures can cause significant discomfort. Long-acting opioid pain medications are commonly used to treat background pain [18]. Premedication with short-acting opioid analgesics before dressing changes or procedures and for breakthrough pain is standard of care [18,19]. Because of the development of drug tolerance or a history of recreational opioid use, both common in burn patients, selection of opioids and doses has to be individualized to patients and may exceed standard dosing guidelines for appropriate symptom control. As the wounds heal, a slow and careful opioid taper is needed to prevent withdrawal. Although there is limited evidence for sole use of nonopioids in severe burn pain, nonsteroidal anti-inflammatory drugs and acetaminophen can be valuable in combination with opioids [18]. Other nonopioid pain medications, like muscle relaxants and antiepileptics, may also be used but have not been well studied.

Strong consideration should also be given to non-pharmacologic pain treatment options. Techniques that demonstrate reduction of pain scores include massage, hypnosis, multimodal distraction techniques, cognitive-behavioral techniques, and music therapy [18,20,21]. Off-the-shelf virtual reality has been shown to reduce acute pain intensity during wound care procedures [22].

Clinicians should note that pain is often a multifactorial experience and therefore should make extended efforts to

treat all possible contributing factors, including pruritus, neuropathy, anxiety, sleep disturbance, depression, and post-traumatic stress.

Pruritus

Moisturizing is encouraged for treatment of pruritus; not only do emollients such as aloe vera and lanolin help improve skin quality, but massaging may provide itch relief by the gate theory and desensitization of the skin [23]. Studies have also shown that topical treatments with colloidal oatmeal, liquid paraffin, EMLA (eutectic mixture of local anesthetics) application, and doxepin cream can be effective for symptom management.

A mainstay of treatment is antihistamines. Histamine is found in abundance in burn wounds and is implicated as a primary mediator of pruritus. Selective H₁ and H₂ antihistamines are generally preferred to nonspecific antihistamines for their limited side effect profile. The use of cetirizine and cimetidine was also shown to be more effective than diphenhydramine and placebo in treatment of postburn pruritus [23]. However, the effect of any antihistamine is often limited. A study of 35 adult patients using diphenhydramine, hydroxyzine, and chlorpheniramine showed similar effect with complete relief in only 20%, partial relief in 60%, and no relief in 20% of patients [24].

Gabapentin has been shown in recent studies to relieve pruritus both as monotherapy and in combination with antihistamines. Some consider postburn pruritus to be a neuropathic process, and the effect of gabapentin may be due to the similar nerve pathways for pain and pruritus. A comparative study of gabapentin, cetirizine, and the combination of the two in 60 patients showed significantly better results in the gabapentin group and the combination group compared with the cetirizine-only group [25]. Pregabalin may be similarly effective but has not been studied in postburn pruritus. Other agents including ondansetron, paroxetine, and naltrexone have shown potential usefulness as adjunctive treatments.

Biofeedback therapy and psychological support may attenuate symptoms. Modalities including laser treatment, massage, and transcutaneous electrical nerve stimulation have also demonstrated positive results and may be useful [26–28]. The use of botulinum toxin injection is under investigation [29].

Wounds

The goal of wound care is to provide a moist, clean environment for reduced bacterial colonization and reepithelialization. Silver-based dressings are the cornerstone of wound management because silver ions have broad antimicrobial activity. Silver sulfadiazine is the best known and most widely used silver-based agent for burns. More recent research suggests that new dressings that elute nanocrystalline silver have better antimicrobial activity, including against methicillin-resistant *Staphylococcus aureus* [30]. These dressings allow longer intervals between dressing changes and increase the patient's comfort. Hydrofiber dressings are another new dressing type that may be less painful and are commonly used for exudative burns [31]. There has also been increasing interest in honey. Several trials comparing honey with traditional dressing in minor burns showed shorter healing times [30]. In general, there

are many dressing options, and dressing selection should take into account knowledge and familiarity of the health care providers.

Hypertrophic Scarring

Compression garments are considered standard of care for treatment of hypertrophic scars. Such garments are initiated with closure of wounds. Initially, pressure wrappings are applied around the affected areas with plastic elastic (ACE), cotton elastic (Tubigrip), or adhesive elastic (Coban) bandages. As edema resolves, the scarred area assumes a more stable shape, and custom-made pressure garments are then fitted. These garments are usually recommended to be worn 23 hours per day for up to 1 to 2 years after a burn. Compliance with this schedule is difficult for many patients. The efficacy of this treatment has not been established in the literature [32], but a number of studies show some improvement in clinical appearance in moderate or severe scarring [33].

Silicone gel sheeting is also considered first-line treatment, but the use of silicone gel sheeting or silicone spray does not demonstrate greater effect compared with pressure garment use alone [34].

Contractures

Positioning and splinting are used to prevent development of contractures and to maximize joint function. Preventive treatment ideally begins on admission to the intensive care unit. The optimal position to minimize contracture development is depicted in Figure 121.2. Particular attention is given to burns that cross joints and exposed tendons. Such joints are at high risk for contracture development and should receive empirical splinting and exercises to maintain range of motion.

Positioning should always be paired with passive or active range of motion exercises to prevent the development of contractures. Range of motion exercises can begin

immediately if the patient has not undergone skin grafting and usually within 1 week after grafting so as not to interfere with graft take. Once a contracture develops, rehabilitation interventions such as splinting, positioning, range of motion exercises, and serial casting have been shown to prevent worsening of the contracture and to improve joint motion [35–38].

Heterotopic Ossification (see Chapter 130)

Conservative treatments include positioning and range of motion exercises. Medications such as nonsteroidal anti-inflammatory drugs or bisphosphonates and radiation therapy are efficacious in the prevention of heterotopic ossification in other disease populations (e.g., spinal cord injury and hip arthroplasty). Their use can be considered, but studies have not examined their effect in burn patients [15].

Hypermetabolism and Deconditioning

After severe burns, survivors often experience a hypermetabolic state with increased catabolism and loss of lean body and bone mass. Meeting nutritional needs, often under the guidance of a dietitian, is an important part of burn care. Enteral feeding may be needed in the acute setting for effective nutrition. Consideration should also be given to nutritional supplementation including vitamins C and D, zinc, and thiamine. Oxandrolone, an anabolic steroid, has been shown in multiple randomized controlled trials, with up to 1 year of use, to increase muscle protein synthesis and weight gain and to decrease hospital length of stay [39]. Because of prolonged hospitalization and the loss of muscle, burn survivors are often severely deconditioned. Long-term exercise training programs are needed for return to pre-morbid functional level. Aerobic and progressive resistance training programs have been shown to be efficacious in improving strength, peak oxygen consumption, lean body mass, and pulmonary function in burn survivors [40].

Psychological Comorbidity

There is limited literature validating treatment of depression, acute stress disorder, post-traumatic stress disorder, and sleep disorders specifically in the burn population [41]. One small study suggests that sertraline may be useful in preventing post-traumatic stress disorder in burned children [42]. Regardless, a large body of evidence documents the efficacy of both pharmacologic and nonpharmacologic treatments of these disorders in other populations [43–45], and psychological conditions in burn patients should be addressed on the basis of these guidelines. Treatment of the burn-injured patient ideally involves collaboration with a mental health team to assist in the diagnosis and treatment of these problems.

Procedures

Botulinum toxin injection is under study as a treatment for postburn pruritus. Another procedure being evaluated is extracorporeal shock wave therapy, which may promote perfusion, increase angiogenesis, and accelerate burn wound healing [46]. Extracorporeal shock wave therapy may also have a role in improving pliability and appearance of

FIGURE 121.2 Optimal positioning to prevent burn contractures.

postburn scarring [47]. However, both these procedures are investigational at this time.

Surgery

Excision and grafting of open wounds are ideally performed within 1 week of injury in clinically stable patients. The goal is to remove necrotic and inflamed tissue for promotion of physiologic wound closure. Studies have shown that early excision and grafting minimizes fluid loss, reduces metabolic demand, and decreases the risk of infection and sepsis [48].

There are many techniques for grafting. Most commonly, partial-thickness burns are treated with split- and full-thickness grafts of epidermis and superficial (papillary) dermis harvested from a nonaffected area (autograft). For larger wounds, mesh grafts or tissue expanders may be used [8]. Allograft, dermal substitutes, cultured epithelial autograft, and Meek technique for micrografts can be used for extensive burns with minimal viable tissue. Deeper burns may require excision and coverage with skin, muscle, or myocutaneous flaps, but these may lead to great deformity [8].

Bone marrow mesenchymal stem cells are under investigation for the possible regeneration of sweat gland-like structures. A few centers have performed face transplants for severe burn patients [49].

In spite of aggressive rehabilitation after a burn injury, significant contractures may still develop. Surgical release of the contracted joint is indicated when there are significant functional impairments despite appropriate conservative treatment.

Surgical resection of heterotopic bone is indicated if it results in significant joint impairment despite a course of conservative treatment or nerve entrapment.

Scarring, disfigurement, and other cosmetic concerns are addressed with reconstructive surgical efforts. Severely burned patients may undergo multiple surgeries during the span of years after their injury. Planning of the myriad possible procedures is a task that should involve multiple members of the burn team, including the patient and his or her family, physiatrist, surgeon, therapists, and mental health professionals.

Potential Disease Complications

Long-term Pain and Pruritus

Pain and pruritus after burn injury are difficult to manage and may become chronic and include physical impairments. Hypersensitivity can be a chronic consequence of burn injury regardless of the severity of the burn [50]. Patients with long-term severe pain and depression are associated with lower physical function at 2 years after injury [51]. This should be taken into account for rehabilitation, return to work, and community integration.

Hypertrophic Scarring

Hypertrophic scarring is common (32%-67%) among those severely burned and is more prevalent among darker

pigmented individuals [52]. When it crosses a joint, it may result in deformities and contractures, leading to psychological, functional, and cosmetic impact [15].

Contractures

Contractures are a common and significant complication of burn injury. They result in cosmetic deformity as well as decreased joint range of motion and function. Contractures are most common at the shoulder, elbow, and knee. Length of stay, inhalation injury, and extent of burn are associated with increased incidence and severity of contracture [53]. Contractures of the hand most commonly occur at the wrist but may involve the metacarpophalangeal, proximal interphalangeal, and distal interphalangeal joints of all digits. Predictors of hand contracture development include concomitant medical problems, total body surface area grafted, and presence of hand burn and hand grafting [54].

Amputation

Amputations may complicate burn injuries and are most commonly associated with electrical injury. Low-voltage (<1000V) injuries most commonly result in amputation of the digits. High-voltage injuries frequently result in major amputation (10%-50%).

Osteophytes and Heterotopic Ossification

Osteophytes are the most frequently observed skeletal alteration in adult burn patients and are most often seen at the elbow.

Heterotopic ossification occurs in approximately 1% of burn injuries and also is most frequently located at the elbow. It commonly is manifested with a decrease in range of motion and may cause impairments in joint function and activities of daily living.

Neuropathy

Mononeuropathies, mononeuropathy multiplex, and peripheral neuropathy have all been documented after burn injury. Risk factors for the development of mononeuropathy include electrical injury, intensive care, and history of alcohol abuse. Compression neuropathy can also result from bulky dressing and improper and prolonged positioning. Mononeuropathy multiplex and peripheral neuropathy in burn patients may be due to a combination of direct thermal injury and the body's systemic response to injury. Risk factors for the development of a generalized peripheral neuropathy include intensive care stay, age, and diabetes [55].

Thermoregulation

Full-thickness burns damage the sweat glands present in the dermal layer. After skin grafting, these glands do not regenerate, leading to impaired sweating in involved areas. For those with larger burns, this may affect thermoregulation, particularly with physical activity in warm climates.

Psychological and Cognitive Complications

Psychological complications are some of the most significant sequelae of burn injury. Acute stress disorder, post-traumatic stress (11%-45%), depression (16%-53%), and sleep disturbances (13%-73%) are common after burn injuries. Pre-existing psychiatric disorders are associated with longer hospital stays and require more surgical interventions. Burn patients, regardless of premorbid psychiatric history, often require long-term psychiatric follow-up.

Cognitive impairments may result from anoxia associated with inhalation injury or hypoperfusion associated with shock. A high index of suspicion is needed for diagnosis and treatment of patients with mild cognitive impairments. Neuropsychological evaluation may assist in diagnosis.

Potential Treatment Complications

Medications used to treat pruritus and pain have diverse side effects. The most common adverse effects of opioids and opioid-like pain medications are nausea, diarrhea, and constipation. Gastrointestinal, hepatic, and renal complications may arise from prolonged use of acetaminophen or non-steroidal anti-inflammatory drugs. Antihistamines used for pruritus have sedating effects. The most common side effects of gabapentin and pregabalin are dizziness and somnolence. Topical treatments, such as silicone gel sheets for hypertrophic scarring, may result in skin maceration or contact dermatitis and rash. Splinting and casting for contractures may cause skin abrasions or pressure sores. Improper positioning and splinting may also lead to compression neuropathies, most commonly seen at the peroneal nerve. Surgical interventions always carry a risk of bleeding, infection, and poor wound healing. This is especially true for burn patients with immune compromise and poor skin integrity.

CHAPTER 122

Cardiac Rehabilitation

Alan M. Davis, MD, PhD

Synonyms

None

ICD-9 Codes

410.00–410.92	Acute myocardial infarction
411.0–411.89	Other acute and subacute forms of ischemic heart disease
412	Old myocardial infarction
413.0–413.9	Angina pectoris
414.0–414.9	Other forms of chronic ischemic heart disease
428.0–428.9	Congestive heart failure
429.2	Cardiovascular disease, unspecified
V42	Cardiac valve replacement status
V42.1	Cardiac transplant status
V43.2	Implantable heart assist system insertion status
V45.81	Aortocoronary bypass status

ICD-10 Codes

I21.3	ST elevation (STEMI) myocardial infarction of unspecified site
I25.2	Old myocardial infarction
I25.9	Chronic ischemic heart disease, unspecified
I20.9	Angina pectoris, unspecified
I50.9	Heart failure, unspecified
I25.10	Atherosclerotic heart disease of native coronary artery without angina pectoris
Z95.2	Presence of prosthetic heart valve
Z95.812	Presence of fully implantable artificial heart
Z95.811	Presence of heart assist device
Z95.1	Presence of aortocoronary bypass graft

Definition

Cardiac rehabilitation is the integrated treatment of individuals after cardiac events or procedures with the goals of maximizing physical function, promoting emotional adjustment, modifying cardiac risk factors, and addressing return to previous social roles and responsibilities. The American Heart Association 2012 update estimates cardiovascular disease prevalence to be 86,200,000 people in the United States; coronary heart disease affects 16,300,000. Of those with coronary heart disease, 7,900,000 have had myocardial infarction, 9,000,000 have angina pectoris, 5,700,000 have heart failure, and 650,000 to 1,300,000 have congenital cardiovascular defects.

Cardiovascular diseases have continued to be the leading cause of mortality in both men and women for more than a century and accounted for 32.8% of all deaths in 2008 [1]. Cardiac rehabilitation supports those who survive to change their lifestyle, to maximize their functional capacity and quality of life, and to decrease their risk for future cardiac events. Cardiac rehabilitation may benefit individuals after acute coronary syndrome, cardiac surgery (coronary artery bypass graft, valve replacement, transplantation, ventricular reduction surgery, correction of congenital heart defect), and compensated congestive heart failure. Cardiac rehabilitation comprehensively addresses risk factor modification and secondary prevention through exercise training, smoking cessation, diet modification, evaluation and treatment of psychosocial stressors, education about the disease process, return to work, and maximizing the medical treatment of comorbidities (such as diabetes mellitus, hypertension, and obesity). In a meta-analysis of exercise-based cardiac rehabilitation programs, cardiovascular mortality was decreased 26%, overall mortality was decreased 13%, and hospital readmissions were reduced 31% compared with usual care in patients with myocardial infarction, percutaneous interventions, coronary artery bypass graft, or known cardiac disease [2].

Symptoms

The individual with a recent cardiac event or procedure frequently complains of decreased endurance for walking or climbing stairs, increased dyspnea during physical activity, and fatigue. If arrhythmia is present, the patient may feel palpitations. Chest pain may accompany physical exertion

or emotional stress. Pain due to surgical incisions of the extremities or chest wall may also be present. Symptoms of heart failure, such as orthopnea and paroxysmal nocturnal dyspnea, may also be present. The person may feel anxious about any type of physical exercise, resumption of sexual activities, and return to work. In many cases, the patient may have symptoms suggesting depression, such as emotional lability, listlessness, poor sleep with frequent or early morning awakenings, and lack of interest in previously enjoyed activities.

Physical Examination

Observation of the patient should look for signs of depression and anxiety. During the examination of the cardiac patient, the clinician will search for signs of complications after the cardiac event or cardiac procedure. Findings of congestive heart failure or fluid overload, such as dyspnea at rest, rales, decreased basilar lung sounds, pleural or pericardial rub, dependent edema, elevated jugular venous distention, or S₃ gallop, should be evaluated. Palpation of decreased or absent pulses in the extremities may suggest the common comorbidity of peripheral vascular disease. Wounds such as sternotomies, vascular harvest sites, chest tube insertion sites, pacemaker insertion sites, and arterial puncture sites should be carefully examined for appropriate healing or signs of infection before exercise programs are prescribed. Manual muscle testing of the extremities provides an indication of the degree of skeletal muscle atrophy due to decreased physical activity. Observation of the patient should look for signs of undue dyspnea during standing and ambulation. The patient should be able to comfortably walk at a slow cadence unless there is marked congestive heart failure or lung disease.

Functional Limitations

Functional limitations due to cardiac disease alone are related to the workload the myocardium can sustain before signs of cardiac dysfunction result. Overall endurance is decreased. The degree and severity of cardiac impairment may limit a patient's physical progress and ultimate maximum level of function. The patient may later return to physically demanding activity, such as heavy labor or competitive tennis (both 8 metabolic equivalents or METs), after rehabilitation that follows uncomplicated coronary angioplasty or stenting without myocardial infarction. However, for the patient who experienced myocardial infarction complicated by congestive heart failure and arrhythmia, the 3 to 5 METs required for walking to a neighbor's home or performing the household chores may be limited by dyspnea. Further compromise of progress is related to the common comorbidities of obesity, cerebrovascular disease, intrinsic lung disease, diabetes mellitus, and peripheral vascular disease. Impairment due to neurologic, rheumatologic, or orthopedic disease may require specific adaptations to allow conditioning and strengthening exercise.

Most patients with uncomplicated cardiac disease are able to ambulate and perform their self-care on discharge from the hospital. A slow stroll and being able to perform basic activities of daily living are not adequate for most individuals and do not predict excellent quality of life

for the individual not referred to rehabilitation. Cardiac rehabilitation maximizes the person's functional restoration, allowing return to work, social roles, and recreational activity. Despite the known benefits of cardiac rehabilitation, the majority of eligible individuals are not enrolled [3].

Emotional stress and an individual's response to it may also produce functional limitations when return to social roles and responsibilities is considered. This may range from anxiety about physical exertion to major reactive depression. Dysfunction such as ischemia, arrhythmia, or even sudden death may be produced by emotional demands such as anxiety [4–6]. This is likely to be due to increased sympathetic drive in the autonomic nervous system, which predisposes the individual to more endothelial damage and cardiac arrhythmias mediated by catecholamines. Depression accounts for approximately the same (35%) risk for myocardial infarction as smoking does [7]. This argues strongly for a clear psychological screening of patients with cardiac events. Patients whose depression was diagnosed and treated by selective serotonin reuptake inhibitors (SSRIs) at the time of their initial myocardial infarction had 43% less new myocardial infarction and cardiac death compared with treatment with non-SSRIs [8]. This is due to an antiplatelet aggregation effect unrelated to aspirin or clopidogrel bisulfate (Plavix).

Diagnostic Studies

The clinician should evaluate the patient's lipid profile to guide pharmacologic and dietary management of hyperlipidemia and hypercholesterolemia. Tight diabetes control may decrease the rate of atheroma formation, and glycosylated hemoglobin (HbA_{1c}) level is used to ascertain the recent success of blood glucose control [9]. Calculation of body mass index assists in targeting ideal body weight.

For the individual with dyspnea on exertion and the comorbidity of lung disease, pulmonary function testing will clarify the contribution of obstructive or restrictive lung disease to the symptoms. Treatable conditions, such as reactive airways and hypoxia during exercise, should be addressed before beginning of cardiac rehabilitation for maximal benefit. Combined ventilatory gas analysis by use of a metabolic cart and electrocardiographic monitoring may differentiate cardiac versus pulmonary exercise-induced dyspnea, chest pain, or fatigue. This may be especially useful in patients with congestive heart failure [10].

A symptom-limited functional exercise test with a metabolic cart is administered 2 to 6 weeks after adequate time for healing and provides the best guide to exercise prescription. The specific timing of exercise testing depends on the amount of myocardium damage, the amount of time needed for healing of surgical sites, the need for return to work, and the practice pattern of the clinician administering the test. As opposed to commonly performed *diagnostic* exercise test protocols, such as the Bruce protocol, that seek to elicit cardiac symptoms, *functional* exercise testing documents work capacity and cardiopulmonary function. Functional exercise testing protocols start at a lower exercise intensity level than common diagnostic protocols do and increase fewer METs per stage. Treadmill testing following a ramp, modified Naughton, or Naughton-Balke protocol is especially well suited to guide cardiac rehabilitation exercise

training because these protocols use smaller increments of intensity that more accurately portray functional capacity. Alternatively, bicycle ergometer protocols may also use smaller gradations of exercise intensity. Bicycle ergometry protocols should be considered for individuals with balance deficits, mild neurologic impairment, or orthopedic limitations.

Echocardiographic, pharmacologic, or nuclear medicine exercise stress testing should be considered for patients with marked lower extremity limitations, severe debility, or electrocardiograms that are difficult to interpret. Most patients have had many electrocardiograms during their hospital stay or evaluation. In the outpatient setting, electrocardiograms should be ordered if there is a change in clinical status, such as new symptoms (e.g., the resumption of angina). For the most part, patients are also monitored by telemetry during at least the initial part of their cardiac rehabilitation.

Patients should be screened for psychosocial stressors, such as anxiety and depression. Besides asking the patient about the symptoms of anxiety, anger, persistent sadness, excessive fatigue, and abnormal sleep architecture, commonly used questionnaires that are easy to administer in an office setting are the Beck Depression Inventory and the State-Trait Anxiety Inventory. Both take only a few minutes to complete and can be used to monitor the effectiveness of treatment.

Treatment

Initial

Cardiac rehabilitation begins with risk factor reduction. Fully integrated cardiac rehabilitation programs enroll the individual into exercise training, dietary interventions, and psychosocial interventions. The referring physician then becomes the supporter of the patient, shifting the patient's lifestyle to making responsible health choices. Consider a discussion of the cardiac rehabilitation experience. The initial medical management focuses on optimizing the cardiac medication regimen to control or to prevent hypertension, ischemia, arrhythmia, hyperlipidemia, fluid overload, or other complications that follow the patient's cardiac event. Diabetes management is also critical to secondary prevention of cardiovascular disease. Concurrent with medical management, the clinician prescribing cardiac rehabilitation must promote choices for healthy living. Each cardiac patient has choices about smoking, diet, exercise, and stress management. Smoking cessation has the highest rates of success by combining participation in a smoking cessation support group with pharmacologic management of the craving due to nicotine addiction. Bupropion combined with a nicotine patch, gum, or lozenges works well. Have the patient begin taking the bupropion hydrochloride (150mg every day for the first 3 days, then 150mg twice daily) 1 to 2 weeks before the chosen date to quit smoking and begin using the nicotine supplement at the time of smoking cessation. This should coincide with the first smoking cessation support group meeting.

Dietary modification has been documented to improve the lipid profile [11]. Ask the patient to keep a food diary for at least 3 days to bring to the cardiac rehabilitation program

Table 122.1 American Heart Association 2006 Diet and Lifestyle Recommendations for Cardiovascular Disease Risk Reduction

Balance calorie intake and physical activity to achieve or maintain a healthy body weight.
 Consume a diet rich in vegetables and fruits.
 Choose whole-grain, high-fiber foods.
 Consume fish, especially oily fish, at least twice a week.
 Limit your intake of saturated fat to <7% of energy, *trans* fat to <1% of energy, and cholesterol to <300 mg per day by choosing lean meats and vegetable alternatives; selecting fat-free (skim), 1%-fat, and low-fat dairy products; and minimizing intake of partially hydrogenated fats.
 Minimize your intake of beverages and foods with added sugars.
 Choose and prepare foods with little or no salt.
 If you consume alcohol, do so in moderation.
 When you eat food that is prepared outside of the home, follow the American Heart Association Diet and Lifestyle Recommendations.

or refer the patient to a registered dietitian for evaluation and education on appropriate heart healthy dietary choices. The American Heart Association revised cardiac diet recommendations of 2006 are substantially more stringent on the saturated fat intake (Table 122.1) [11]. The dietitian may recommend the American Heart Association diet, but other choices could be the Mediterranean diet or the lacto-ovovegetarian diet. None of these three diets has been shown to be superior, and the choice of diet is based primarily on the patient's ability to follow the diet.

The individual with cardiac disease often needs to learn strategies to decrease the emotional stress of anxiety and depression. Patients with either of these based on the original screening should be treated. SSRIs treat both components fairly well with few side effects. A referral for counseling with a mental health professional can provide patients with an assortment of tools to learn relaxation and provides a forum for the discussion of emotional symptoms surrounding cardiac events in their life. Women have a higher rate of anxiety and psychosomatic complaints than do men beginning cardiac rehabilitation and can benefit from greater attention to psychosocial interventions [12,13]. In the busy clinic, the clinician can teach the individual a simple stress reduction technique. A relaxation response documented by augmented parasympathetic activity has been noted during the simple exercise of paced breathing. Ask the patient to pace his or her breathing, using a clock, for 5 to 10 minutes twice daily. The patient should time inhalation and exhalation equally for 3 to 5 seconds each while avoiding air hunger or hyperventilation. Once he or she performs this exercise with facility, additional relaxation can be achieved from further slowing of the breathing rate or prolonging the period of exhalation [14].

Return to sexual activity should be frankly discussed with patients and their sexual partners to decrease their anxiety about sexual activity after a cardiac event [15]. Sexual activity between couples with a long-standing relationship requires 3 to 5 METs. Extramarital sex causes higher energy demands. In a statement from the American Heart Association, sexual activity is safe to be resumed, although erectile dysfunction medications should be avoided in patients using nitrates for angina due to coronary artery disease [16].

Return to work and recreational activities should be based on patients' clinical status and their previous work. In a meta-analysis of European cohort studies, significant job-related emotional stress also increased the risk for cardiac events [17]. The exercise test performance predicts the level of vocational work capacity. If the patient's work capacity is only 3 to 4 METs or less, return to work may be unrealistic. Even self-care activities are likely to produce symptoms at this low level. With a capacity of 5 to 7 METs, the person should be able to perform sedentary work and most domestic roles. If the person can exercise beyond 7 METs, most types of work can be performed without restriction, except those involving heavy physical labor. For recreational activity, the MET level required should be evaluated before return to play is recommended. The *Compendium of Physical Activities* can be used to guide return to work and recreation activities and can also be accessed online (<https://sites.google.com/site/compendiumofphysicalactivities/>) [18]. The following are some common recreational activities and their MET requirements: walking at a moderate pace, 3.5; tennis, 4.5 to 8; golf, 4 to 5; downhill skiing, 4 to 8; bowling, 3 to 5; and volleyball, 3 to 4.

Rehabilitation

Cardiac rehabilitation begins in the hospital with early mobilization, dietary instruction, and medication and disease process education. Many patients have relatively minimally invasive procedures without the loss of heart muscle function, such as coronary stent placement during acute angina. The following recommendations assume some kind of cardiac debility.

Consider a short stay in acute inpatient rehabilitation if the person is stable but unable to perform basic mobility and self-care tasks at a household level. Recommend a self-directed walking program if the patient is unable to begin a supervised exercise training program on discharge from the hospital. This should be reserved for individuals with an uncomplicated hospital course and for whom exercise is not contraindicated (Table 122.2). The patient should walk primarily on level surfaces at a slower pace with the goal of

10 to 30 minutes of walking at least three to five times per week at an intensity that will allow talking. Ask patients to keep a walking journal and review it with them.

If no significant cardiac damage has occurred, such as after angioplasty, the period of convalescence may be shortened on the basis of the clinician's judgment and considerations such as the individual's need to return to previous pursuits.

Physical training with referral to cardiac rehabilitation begins at the end of the convalescence period. Ideally, this is based on functional exercise testing described in the preceding section on diagnostic studies. Arguments have been made that exercise testing at this stage does not improve the outcome or safety of a supervised cardiac rehabilitation therapy program, but functional exercise testing is still the "gold standard." [19] Exercise prescription includes type, target intensity, frequency, and duration of exercise. Aerobic exercises, such as walking and bicycling, are the mainstay of most programs. Prescribe aerobic exercise intensity on the basis of heart rate, exercise intensity (METs), or perceived exertion (Table 122.3). The visual analog Borg scale rates perceived exertion (Fig. 122.1) and has been shown to correlate linearly with heart rate and oxygen consumption [20]. For the patient taking beta blockers, perceived exertion is a good guideline as the heart rate response is somewhat blunted. The frequency of exercise sessions is usually three to five times per week.

Aerobic exercise sessions begin with a warm-up phase of 2 to 5 minutes at a lower intensity of exercise to limber the joints, to open collateral circulation, and to decrease peripheral vascular resistance. The stimulus or conditioning phase may be continuous or discontinuous, with the 3- to 12-month goal of at least 20 to 30 minutes of aerobic exercise. This may be broken down as a discontinuous exercise with rest breaks between periods of conditioning exercise. A cool-down phase at a lower intensity of exercise will prevent hypotension and, later, joint pain. Duration of aerobic exercise sessions depends on the individual's level of fitness. For the markedly debilitated patient, 3 to 5 minutes in the target range will provide benefit initially. The deconditioned individual should be progressed during 4 to 12 weeks to this 20- to 30-minute stimulus phase. Electrocardiographic monitoring during aerobic exercise is recommended for patients with low ejection fraction, abnormal blood pressure response to exercise, ST-segment depression during low-level exercise testing, or serious ventricular arrhythmia [21].

Strength training or circuit training with resistance exercises adds skeletal muscle strength and facilitates building of local muscle endurance for those with good left ventricular function. This should especially be considered for the cardiac patient who may be returning to a physically demanding job. Patients who use free weights should begin with the lowest weight that produces a perceived exertion of 11 to 13 after 10 to 15 repetitions (see Fig. 122.1). One to three sets will build strength. This should involve enough different exercises to include all major muscle groups of the upper and lower extremities.

The clinic-based supervised exercise program typically lasts 1 to 3 months, with the exercise prescription upgraded monthly. Monthly reevaluation should include consideration of increasing the stimulus-phase intensity or duration of aerobic exercise. After 2 to 3 months of a conditioning

Table 122.2 Possible Contraindications for Entry into Inpatient or Outpatient Exercise Programs

Unstable angina
Resting systolic blood pressure > 200 mm Hg
Resting diastolic blood pressure > 100 mm Hg
Orthostatic blood pressure drop or drop during exercise training of 20 mm Hg
Moderate to severe aortic stenosis
Acute systemic illness or fever
Uncontrolled atrial or ventricular dysrhythmias
Uncontrolled sinus tachycardia (120 beats per minute)
Uncontrolled congestive heart failure
Third-degree atrioventricular block
Active pericarditis or myocarditis
Recent embolism
Thrombophlebitis
Resting ST displacement (> 3 mm)
Uncontrolled diabetes
Orthopedic problems that prohibit exercise

From American College of Sports Medicine. Guidelines for Exercise Testing and Prescription, 4th ed. Philadelphia, Lea & Febiger, 1991.

Table 122.3 Cardiac Rehabilitation Exercise Prescription

Type	Aerobic	Treadmill	Bicycle (circle one)
Include	Strength training?	Yes No	(circle one)
Intensity: Based on heart rate			
Target heart range			
70% to 85% of maximum heart rate if the patient is not taking β -adrenergic blockade			
85% maximum completed on treadmill if the patient is taking β -adrenergic blockade			
High resting heart rate (HR), by exercise testing results (Karvonen formula):			
Target HR=resting HR + $[(HR_{max} - HR_{rest}) \times (60 + MT_{max}/100)]$			
Intensity: Based on workload			
Target 66% MET level completed on treadmill testing			
Target 25 watts or 150 kpm less than completed stage on bicycle ergometer testing			
Intensity: Based on perceived exertion			
Borg scale target 11 to 15			
Warm-up phase			
Treadmill ambulation at ____ speed ____ grade for ____ minutes.			
Bicycle ergometry at ____ kpm/watts for ____ minutes.			
Check blood pressure, pulse rate, and perceived exertion.			
Advance to stimulus phase.			
Stimulus phase			
Treadmill ambulation at ____ speed ____ grade ____ minutes with/without rest. Repeat ____ sets.			
Bicycle ergometry at ____ kpm/watts for ____ minutes with/without rest. Repeat ____ sets.			
Check blood pressure, pulse rate, and perceived exertion.			
Advance to cool-down phase.			
Cool-down phase			
Treadmill ambulation at ____ speed ____ grade for ____ minutes.			
Bicycle ergometry at ____ kpm/watts for ____ minutes.			
Check blood pressure, pulse rate.			
Frequency	3 times per week		
Duration	1 hour per visit for 12 weeks		

FIGURE 122.1 Borg scale of perceived exertion. (From Borg G. Perceived exertion as an indicator of somatic stress. *Scand J Rehabil Med* 1970;2:92-98.)

exercise program, the individual should have the ability to achieve 7 to 8 METs of sustained exercise. Once the patient has achieved this goal, repeat of the exercise test will show the level of improvement and guide the transition to a self-directed maintenance program. The patient may choose to follow his or her target heart rate or exertion level during exercise.

The benefits of exercise training include increased maximum oxygen uptake, increased endurance for activities of daily living, increased functional capacity, decreased heart rate during exercise, decreased rate-pressure product, decreased fatigue, decreased dyspnea, and decreased

symptoms of heart failure. Exercise training reduces atherogenic and thrombotic risk factors by managing or preventing excess body weight, increasing high-density lipoprotein cholesterol concentration, decreasing plasma triglyceride levels, decreasing platelet aggregation, and improving glucose levels. Myocardial perfusion may be improved by increased coronary blood flow. The progress of coronary atherosclerosis may be slowed or possibly reversed.

Home-based cardiac rehabilitation programs should be considered for less medically complex patients unable to attend outpatient programs. A review comparing home-based versus center-based rehabilitation for low-risk cardiac patients after uncomplicated myocardial infarction or coronary artery bypass graft showed no difference in morbidity and mortality, health-related quality of life, or modifiable risk factor reduction [22].

Psychosocial interventions provide specific tools to live with emotional stress, depression, anxiety, and returning to work. Adjunct treatment with medication may be necessary if counseling and lifestyle management are inadequate alone.

Procedures

Medically stabilized cardiac patients need few procedures. Large pulmonary effusions may decrease exercise capacity, requiring the need for thoracentesis. Interventional cardiology procedures may be needed for acutely occluded stents, angioplasty, or grafts. For the patient with significant arrhythmias, pacemaker or defibrillator placement or adjustment may be necessary. The patient with worsening cardiac symptoms may need to repeat coronary angiography or other diagnostic testing if medication adjustment is unsuccessful.

Surgery

Surgical interventions may be needed for failed coronary bypass vascular grafts, infected wounds, or pseudoaneurysms at arterial puncture sites. Permanent pacemaker or implantable defibrillators may be necessary for individuals with arrhythmias not controlled with medications.

Potential Disease Complications

The most common cause of mortality in the United States is cardiac disease. Decreased exercise tolerance and decreased work capacity are the most common functional impairments. Medical complications include congestive heart failure, arrhythmia, repeated infarction, and possible closure of coronary artery grafts and stents or angioplasties. Sternotomies may not heal or become infected, requiring surgical débridement or revision. Because coronary artery disease is associated with generalized atherosclerotic vascular disease, one should be aware of possible stroke, peripheral vascular insufficiency, and other end-organ manifestations of compromised vascular supply. Even with referral to cardiac rehabilitation, individuals may still experience loss of social roles, vocational barriers, and difficulty with emotional adjustment despite excellent physical improvement and appropriate psychosocial interventions.

Potential Treatment Complications

There is a slight risk of precipitation of a cardiac event during cardiac rehabilitation. In one study, the risk of a significant cardiac event during exercise training, such as new infarct or death, occurred at a rate of 1/50,000 to 1/120,000 person-hours of exercise [23]. Preventing the enrollment into cardiac rehabilitation of patients who are not medically stabilized can minimize the risk. Exercise testing has relative and absolute contraindications that should be followed. These contraindications have been elucidated in great detail elsewhere [10]. In general, however, do not test patients with unstable angina, malignant cardiac arrhythmia, pericarditis, endocarditis, severe left ventricular dysfunction, severe aortic stenosis, or any other acute noncardiac disease. Common adverse treatment events are postexercise hypotension or arrhythmia and muscle or joint pain. These are minimized if exercise testing guides the cardiac rehabilitation prescription.

CHAPTER 123

Cancer-Related Fatigue

Andrea Cheville, MD, MSCE

Synonyms

Cancer-related fatigue syndrome
Paraneoplastic dysfunction

ICD-9 Codes

357.6 Polyneuropathy due to drugs
780.79 Other malaise and fatigue
781.2 Abnormality of gait

ICD-10 Codes

G62.0 Drug-induced polyneuropathy
R53.81 Other malaise
R26.9 Abnormalities of gait and mobility

Definition

Cancer causes one in four deaths in the United States and is a major public health problem worldwide. Projections for 2013 were that more than 1,660,290 new cancer cases would be diagnosed and that more than 580,305 patients would die of cancer [1]. Cancers vary widely in prognosis, natural history, management, treatment responsiveness, adverse sequelae, and associated physical impairments. As a consequence, cancer rehabilitation is not amenable to one-size-fits-all treatment approaches. Physical impairments vary with the location and stage of cancer as well as by the type of treatment. For example, cancers of the head and neck may require neck dissection and irradiation. Common sequelae include shoulder dysfunction and fibrosis of cervical soft tissue. In contrast, primary breast cancer treatment may cause myofascial pain and upper extremity swelling. The reader is referred to chapters specific to these conditions and anatomic locations (e.g., scapular winging, lymphedema).

A more uniform approach can be applied to the management of cancer-related fatigue (CRF). The National Comprehensive Cancer Network defines CRF as a distressing,

persistent, subjective sense of physical, emotional, or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning [2]. CRF is the most common cancer-associated symptom among the more than 12 million cancer survivors in the United States [3]. Its effects can be overwhelming and, depending on the nature and treatment of the cancer, can limit the lives of as many as 70% of disease-free survivors [4–7]. Whereas severe post-treatment CRF is particularly common among lung cancer survivors [8,9], high levels of persistent CRF are also reported among the survivors of most malignant neoplasms, including but not limited to those of the breast, brain, head, and neck and childhood malignant neoplasms [7–21]. CRF, even at its mildest levels, affects all health-related quality of life domains [4,22–24]. On a vocational level, CRF intensity predicts failure to return to work [4,25–27], and it is estimated that 1 million cancer survivors may be receiving disability payments as a consequence of its persistence [28]. On a general level, multiple investigators have found that increased CRF is considered an important unmet care need by patients [29–31] and explains a significant proportion of performance and mobility degradations [32–38] across a wide range of cancers [39–42]. Not surprisingly, the indirect costs associated with patients with CRF are increased, with research showing that patients with CRF visit general practitioners 50%, specialists 350%, physical therapists 130%, and complementary caregivers 520% more often than those without the condition do [4,43,44]. Fortunately, effective CRF treatment has been shown to improve vocational productivity and performance of activities of daily living while reducing family stress and caregiver burden [45].

Symptoms

Before formal evaluation is undertaken, it is important to establish the patient's current place on the cancer trajectory, which influences all elements of the history and physical examination. Three important distinctions must be made:

1. Is the patient receiving active treatment?
2. Does the patient have residual cancer?
3. Is the patient deemed curable?

The willingness and capacity of patients to engage in the rehabilitation process will be reflected in the answers to these questions.

A characteristic constellation of symptoms should not be anticipated in patients' reporting of CRF. As emphasized before, patients' neoplasms, treatment regimens, and disease trajectories are variable. CRF may therefore be manifested differently, contingent on the particulars of each case. Patients' descriptions of their fatigue may be inconsistent and, at times, puzzling to clinicians. Any of the following subjective complaints should raise concern about possible CRF: weakness (generalized or proximal), dyspnea on exertion, orthostatic hypotension, sedation, hypersomnolence, exertional intolerance, or cognitive compromise (e.g., attention or concentration deficits, short-term memory dysfunction). Patients may report the sensation that their legs are leaden or that they are walking through water. Validated self-report fatigue scales (e.g., Brief Fatigue Inventory, Functional Assessment of Cancer Treatment—Fatigue, Profile of Mood States) can be exceedingly useful to quantify severity of symptoms and to monitor treatment response [46]. A brief screen for depression or other mood disorders is essential, and validated screening tools are widely available.

Patients' cancer histories warrant attention, including prior and ongoing radiation therapy and chemotherapy as well as any surgical procedures. Awareness of a patient's primary cancer will shift the focus toward particular causes of symptoms. Information comparable with that solicited through a good pain history should be elicited for fatigue: acuity of fatigue onset, activity- or treatment-related precipitants, diurnal fluctuation, associated symptoms (e.g., pain, nausea), progressive worsening or improvement, exacerbating and alleviating factors, and prior treatments and degree of response. Questions about sleep patterns, sleep hygiene, and daytime napping are useful. Reports suggest that frequent daytime napping may actually worsen fatigue [47].

The extent to which fatigue limits vocational, avocational, and familial pursuits as well as autonomous mobility and self-care should be comprehensively reviewed. Because fatigue most commonly interferes with activities requiring stamina and exertional tolerance, changes in a patient's comfortable walking distance, duration of physical activity, and willingness to climb stairs will help characterize the impact of fatigue.

Physical Examination

Special tests are rarely indicated on physical examination. Rather, clinicians should perform a comprehensive evaluation with emphasis on musculoskeletal and neurologic elements. Assessment of range of motion, gait (including tandem), static and dynamic balance, and ability to squat repetitively may identify potential contributing factors amenable to therapeutic exercise. Examination may reveal evidence of congestive heart failure or pulmonary compromise. Signs of hypothyroidism should be sought, particularly in patients irradiated for head and neck cancers. For patients without evidence of cancer, the neurologic examination findings should be normal beyond chemotherapy-related peripheral neuropathy. Weakness in proximal hip and shoulder musculature suggests steroid myopathy. Identification of new neurologic deficits should trigger evaluation for malignant progression or emerging treatment toxicity. The mental

status examination may reveal evidence of compromised arousal, attention, memory, or concentration, particularly in patients who have received whole-brain radiation therapy or intrathecal chemotherapy.

Functional Limitations

Although fatigue is rarely so severe that it undermines basic mobility or performance of activities of daily living apart from the palliative context [48], evaluation of these functional domains is integral to comprehensive evaluation. Severe functional compromise may be a red flag, contingent on the clinical context that triggers evaluation for significant comorbidity or recurrent cancer. Ambulation for moderate distances may produce limiting dyspnea in patients with cancer-related cardiac or pulmonary dysfunction. Patients with steroid myopathy or generalized muscle weakness may have difficulty in rising from low surfaces, such as a toilet, soft chair, or car seat. These patients may also demonstrate decreased ability to independently complete their activities of daily living in a reasonable time frame. As suggested previously, many patients describe generalized heaviness of the limbs and global decrements in activity level without precise functional limitations.

Dysfunction in social, vocational, psychological, and sexual domains may be present. Patients should be questioned about compromised social interactions, sleep, and intimacy as well as work-related and leisure pursuits. Many patients abandon their avocational activities as a consequence of fatigue, with the potential for isolation and secondary depression. Patients with cognitive deficits related to radiation therapy or chemotherapy may experience difficulty in maintaining their vocational productivity. Financial and domestic management skills may be compromised as well.

Diagnostic Studies

Diagnostic tests should be informed by patients' symptoms and findings on clinical examination. Dyspnea should be assessed with pulse oximetry during activity, chest radiography, and electrocardiography. Patients who exhibit severe dyspnea with minimal activity may have pulmonary fibrosis. Definitive diagnosis may require computed tomographic scanning. Positron emission tomography may help distinguish fibrosis from cancer involving the lung parenchyma. Patients with cancer are at an elevated risk for venous thrombosis; therefore, a venous duplex study and possibly a ventilation-perfusion scan should be considered for persistent shortness of breath. Patients who have received doxorubicin (Adriamycin) or trastuzumab (Herceptin) should be evaluated with a multigated acquisition scan to rule out possible chemotherapy-related cardiac toxicity. Most patients will have undergone multigated acquisition screening before the administration of chemotherapy. The results of baseline tests can be compared with new evaluations for evidence of deterioration. Pericardial effusions may be a consequence of malignant spread or radiation-induced irritation or occur as a paraneoplastic phenomenon. An echocardiogram should be obtained for patients with a suggestive history and physical examination. Patients reporting insomnia or a failure to feel rested after

a night's sleep may benefit from a sleep study to rule out sleep apnea or related disorders.

Serologic evaluation may include thyroid-stimulating hormone concentration (to screen for thyroid myopathy in patients who have received irradiation to the anterior neck), calcium concentration, electrolyte values (Addison disease may occur with adrenal metastases or irradiation), hemoglobin concentration, and hematocrit. Hypercalcemia or persistent mechanical pain should be evaluated with a bone scan or plain films. *Multiple myeloma and malignant neoplasms producing lytic metastases may fail to generate an abnormal bone scan despite diffuse skeletal involvement.* Blood levels of centrally acting medications (e.g., tricyclic antidepressants, anticonvulsants) may warrant assessment in patients who describe fatigue with a significant cognitive dimension.

For patients with focal neurologic deficits, imaging of those portions of the neural axis implicated on physical examination should be performed. Magnetic resonance images should be obtained with gadolinium. Steroids administered in conjunction with chemotherapy may be of sufficient doses to cause myopathy. Electrodiagnostic studies can rule out alternative, treatable sources of neurologic compromise.

Patients complaining of generalized cognitive dysfunction may benefit from neuropsychological evaluation. Cognitive deficits have been detected after chemotherapy [49]. Multifocal brain metastases may be manifested with a global decrement in mental acuity and capacity to attend. Enhanced computed tomographic scanning of the head may be warranted when there is a high clinical probability of brain metastases (e.g., patients with melanoma, breast or lung cancers).

Screening for depression, anxiety, and other psychological distress is integral to the CRF evaluation. The Patient Health Questionnaire (PHQ-9) is a brief and valid screen for use in cancer populations. The PHQ-9 distinguishes both the presence and severity of depression [50]. The Generalized Anxiety Disorder (GAD-7) screen is another valid measure with low respondent burden that can be facily integrated into routine history taking [51].

Differential Diagnosis

- Depression
- Nutritional insufficiency
- Anemia
- Infection
- Metabolic or endocrine abnormality (e.g., hypercalcemia, hypothyroidism, adrenal insufficiency)
- Steroid myopathy
- Medication side effects
- Chemotherapy- or radiation therapy-induced cognitive dysfunction
- Cachexia
- Pulmonary parenchymal disease, bleomycin toxicity, radiation therapy-induced fibrosis
- Pleural or pericardial effusion
- Doxorubicin- or trastuzumab-related cardiotoxicity
- Disturbed disorder
- Neural axis compromise (e.g., brain metastasis, epidural metastasis, brachial or lumbosacral plexopathy)

Treatment

Initial

It is important to address any remediable endocrine, hematologic, metabolic, or physical abnormalities before initiation of treatment (e.g., exercise that targets fatigue). Uncontrolled pain mandates the initiation or modification of analgesics. Opioid-based pharmacotherapy has emerged as the cornerstone of cancer pain management [52]. Secondary infections related to cancer therapy-induced neutropenia must be treated before aerobic conditioning can begin. The discovery of disease progression may warrant initiation or alteration of an antineoplastic regimen or the administration of radiation therapy. Cardiac toxicity may improve after the initiation of digoxin or medications to reduce afterload. Anemia generally responds to therapy with recombinant erythropoietin with associated improvements in the patient's function and quality of life [53]. Patients with pulmonary fibrosis induced by radiation therapy or chemotherapy and those who have undergone lobectomy or pneumonectomy may require supplemental oxygen during rehabilitative efforts. Nutritional evaluation may be needed for cachectic or hypoproteinemic patients.

Rehabilitation

Well-powered, randomized, controlled trials have established that both strengthening and aerobic exercise can, regardless of the phase of the disease, effectively reduce the effects of CRF [54–63]. Modest exercise intensity levels (e.g., 60% of maximum oxygen consumption up to 5 days per week) suffice and are well tolerated by patients irrespective of treatment phase. A significant proportion of positive studies have used home-based exercise approaches [57–61], which work in noncancer populations suggests may be particularly effective in enhancing long-term adherence [64–66]. It is significant that whereas structured programs, particularly when they are augmented with supportive counseling [60,61], have proved highly efficacious, a more flexible program lacking specific exercise recommendations has not [67].

Exercise is not the only beneficial approach. Psychoeducational interventions emphasizing activity and stress management [68–71], mindfulness training [72], coping skills and problem-solving training [68,73], and cognitive-behavioral therapy [74] have also been shown to be capable of significantly reducing CRF. Although randomized, controlled trials of supportive and exercise therapies in isolation have yielded mixed results [75–79], supportive therapy alone may be effective when CRF is the principal therapeutic focus [79]. To date, no trial that has combined aerobic exercise with structured psychological support has failed to note significant improvements in fatigue [58,60,61]. However, treatments may be less effective in the advanced stages of cancer [80].

Unfortunately, the patient volumes, staff expertise, and infrastructure necessary to support these group and 1:1 interventions are available only at large tertiary medical centers. According to the National Cancer Institute estimates, only about 15% of U.S. cancer patients are diagnosed and treated at these centers, suggesting that the remaining 85% are being treated at facilities incapable of providing effective CRF management programs.

The literature supports interval training at 50% to 70% of the heart rate reserve or while working at an exertion of 11 to 14 (moderate intensity) on the 6 to 20 perceived rate of exertion scale. The intensity of the exercise program depends on baseline fitness levels, intensity of cancer treatment, and stage of cancer treatment. While the patient is undergoing treatment, most studies recommend decreasing the intensity to the lower end of the heart rate range. Once active chemotherapy or radiation therapy has been completed, the program may be progressed toward the higher end of the range. The intensity must also take into account daily laboratory values and patterns of fatigue associated with treatment. For example, fatigue peaks within the middle and end of the radiation therapy cycle, and the program should account for this pattern. Finally, duration and frequency should closely match the American College of Sports Medicine guidelines, which recommend that patients with cancer exercise for a total of 20 to 30 minutes three to five times per week [81].

Exercise precautions for cancer patients are seldom evidence based. They vary significantly between institutions and clinicians. The following limitations are conservative suggestions and should not be interpreted as absolute exercise contraindications. Aerobic and resistive exercise should be carefully reviewed if not discontinued when platelet levels fall below 10,000/ μ L. Contact and high-impact sports should be avoided when platelet levels fall below 50,000/ μ L or in patients with primary or metastatic bone disease. Light exercise is allowed when hemoglobin concentration is less than 8 g/dL, with patients closely monitored for symptoms. Therapeutic activities should be restricted to indoor exercise for patients at nadir with an absolute neutrophil count below 500/ μ L. Exercise should be deferred for febrile patients with temperatures above 101.5°F.

In addition to aerobic conditioning, referral to occupational and physical therapy for training in energy conservation strategies, use of adaptive equipment, and progressive resistive exercise will benefit appropriate patients. Instruction in compensatory strategies for mobility and performance of activities of daily living can optimize autonomy within the constraints imposed by CRF. Adaptive equipment, such as canes, crutches, and walkers, may improve mobility; provision with adaptive devices, such as long-handled shoehorns and reachers, may facilitate independent self-care activities. Interventions for mobility and performance of activities of daily living benefit even end-stage cancer patients. For these patients, education and empowerment of caretakers may emerge as the primary therapeutic focus.

A psychiatric consultation may be indicated if depression emerges during evaluation. All nonessential centrally acting drugs should be eliminated. Pain medications should be chosen to minimize neuropsychological toxicity. Among the opioids, hydromorphone, fentanyl, and oxycodone have fewer active metabolites than morphine sulfate [82]. Their use may be associated with a more tolerable side effect profile in the elderly and patients with renal impairment. Pharmacologic approaches for cancer fatigue center predominantly around the administration of psychostimulants. The utility of these agents is equivocal since controlled trials of methylphenidate and pemoline have produced mixed results [83].

Procedures

Patients with pleural or pericardial effusions will benefit from percutaneous drainage of the fluid. Pleurocentesis or pericardiocentesis may be required to prevent the reaccumulation of effusions. Percutaneous stenting procedures have become commonplace when tumor compression narrows the lumen of ureters, bile ducts, bronchi, or blood vessels with adverse physiologic sequelae. When cancer pain cannot be adequately managed with systemic therapy or if side effects become untenable, neuraxial analgesic delivery may restore normal arousal, energy, and cognition [33]. Radiation therapy may be used palliatively to treat pain or to reduce tumor bulk that is compressing neurologic structures.

Surgery

Cancer patients with deconditioning and fatigue may benefit from surgical debulking of tumor or resection of isolated lung, liver, bone, or brain metastases. Fatigue, however, is not an independent indication for surgery. If focal sensory or motor deficits result from tumor compression of neural pathways, emergent resection may be required.

Potential Disease Complications

Patients commonly deteriorate functionally because of incremental tumor burden and morbidities as their cancers advance. Consequences of malignant progression may include new or worsening neurologic deficits, dyspnea, cognitive deterioration from intracranial metastases or radiation therapy-induced changes, pathologic fractures, visceral obstruction, and somatic pain syndromes.

Potential Treatment Complications

Potential complications of anticancer modalities are extensive. Radiation therapy can cause fibrosis, neurologic compromise, and worsening of CRF. Chemotherapy can similarly exacerbate CRF. Various chemotherapeutic agents have the capacity to impair cognitive, renal, pulmonary, cardiac, and neurologic function. The pharmacologic agents used to manage cancer-associated symptoms and pain can adversely affect neurologic, gastrointestinal, and urinary function as well as exacerbate peripheral edema and CRF.

Complications associated with rehabilitative interventions are few when strategies are used appropriately. Patients with bone-avid cancers (e.g., lung, prostate, breast, thyroid, multiple myeloma, and renal) are at risk for pathologic fractures, particularly those with lytic metastases. A recent bone scan or skeletal survey should be reviewed before initiating an exercise program.

Cancer patients should generally be considered more susceptible to common exercise-induced complications. Overly aggressive aerobic conditioning or strengthening programs may worsen CRF. Uncustomary exertion may aggravate chemotherapeutically induced electrolyte and fluid imbalances. Therapeutic regimens for cancer patients should be adapted and scrutinized accordingly.

Definition

Cerebral palsy (CP) is a neurodevelopmental condition caused by a nonprogressive lesion of the brain. Whereas CP is typically diagnosed early in life and brain lesions are not progressive, it continues to bear effects that may worsen throughout the life span.

Many definitions of CP have been proposed. The most recent was agreed on in 2006 after review of the proposed definition by the International Workshop on Definition and Classification of CP. Through this review, it was decided that CP would be used as a clinically descriptive term instead of an etiologic diagnosis, defined as follows:

Cerebral palsy describes a group of permanent disorders of the development of movement and posture, causing activity limitation, that are attributed to nonprogressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of cerebral palsy

are often accompanied by disturbances of sensation, perception, cognition, communication, and behavior, by epilepsy, and by secondary musculoskeletal problems [1].

Prevalence

The prevalence of CP has been reported to range from 1 to 3 per 1000 live births [2–4]. YeARGIN-Allsopp and coworkers [3] reported a higher incidence of CP in boys compared with girls, with a ratio of 1.4 to 1. The same study found a higher prevalence of CP in black compared with white children or those of Hispanic descent [3]. Subsequent studies confirmed this finding [5–8]. Maenner and colleagues [8] also evaluated mobility. In this study, the majority of children were ambulatory, followed by those who were nonambulatory or had limited mobility, with the smallest number walking with an assistive device.

Mobility difficulties have been associated with increased mortality of children with CP. In a study by Strauss and coworkers [9], those who were categorized as having poor mobility (defined by the inability to lift the head while in a prone position) had twice the mortality rate as those with high mobility (defined by the ability to roll or to sit). However, the same study found that the overall mortality rate of children with severe disabilities is declining by an estimated 3.4% per year.

Etiology

Risk factors for CP can be divided into pre-pregnancy risk factors, maternal disease, and pregnancy related. Pre-pregnancy risk factors, which have been associated with thrombosis and perinatal stroke, include advanced maternal age and primiparity, respectively. Maternal diseases such as diabetes, anemia, hypertension, epilepsy, thyroid dysfunction, and chronic renal disease have also been associated with CP. Associations have been found with multiple gestation (twins, triplets) and delivery factors such as assisted fertilization, plurality, placental disease, bleeding during pregnancy, preeclampsia or eclampsia, intrauterine exposure to infection (urinary tract infections, sexually transmitted diseases, and rubella, among others) or maternal fever in labor, restricted or excessive growth for gestational age, abnormal presentation at time of delivery, rupture of membranes longer than 24 hours before delivery, and induced labor [10,11]. Apgar score of less than 7 at 5 minutes, low birth weight, and gestational age of less than 37 weeks are also risk factors for CP.

Although many risk factors for CP exist, the actual cause is a cerebral abnormality. CP may be caused by neonatal encephalopathy from hypoxic-ischemic events, ischemic stroke, or congenital malformations [12].

Classification

CP has been classified on the basis of the dominant presentation of tone or movement into spastic, dyskinetic (dystonic or choreoathetotic), and ataxic [1]. It has been further divided on the basis of limb involvement into unilateral (or hemiplegia) or bilateral (either diplegia or quadriplegia) [1,13]. It is also recommended to account for accompanying impairments and anatomic findings in classifying CP [1].

Neuroimaging findings have been associated with specific CP subtypes. Bilateral spastic CP has most frequently been found to have periventricular white matter changes on imaging. On the other hand, unilateral spastic CP has been associated with periventricular white matter lesions, periventricular gliosis, focal cortical dysplasia, and unilateral schizencephaly. Athetoid CP has been associated with cortical or deep gray matter lesions. In ataxic CP, lesion patterns are less common, but imaging may demonstrate cerebellar malformations [14].

Symptoms

Whereas CP has a profound effect on the musculoskeletal system, it can be accompanied by myriad symptoms affecting other body systems. Symptoms vary by disease severity and may include intellectual disability, seizures, learning disorders, skeletal deformities, pain, abnormal tone, weakness, developmental delay, poor dental health, difficulties with bowel and bladder management, difficulties with oral-motor control, tremors, difficulties with sleep, and difficulties with mood. Here we discuss the body systems most commonly affected by CP.

Head, Eyes, Ears, Nose, and Throat

CP may be accompanied by visual deficits, sensorineural hearing loss, poor oral-motor control, and poor dentition. Vision may be hindered by strabismus (esotropia) or nystagmus. Depending on etiology, there may also be concern for retinopathy of prematurity. Difficulty with oral-motor control may lead to excessive drooling, dysphagia, dysarthria, or aphasia [15,16].

Cardiovascular

Cardiovascular disease may be of concern as those with CP age. Increased circulatory system disease in adult CP cases compared with age-matched peers has been reported [17].

Pulmonary

Many CP-associated symptoms can lead to deterioration of the pulmonary system. Dysphagia may lead to aspiration, which in turn can lead to pneumonia. Changes in tone and development of scoliosis can lead to decreased vital capacity and restricted airway disease. As patients age with CP, there may be an increase in respiratory illnesses, including pneumonia, influenza, and chronic obstructive pulmonary disease [16,17].

Gastrointestinal and Genitourinary

Along with oral-motor impairment, feeding may be affected by swallowing dysfunction. A high incidence of gastroesophageal reflux disease has also been reported [16]. This may be due to associated hiatal hernias, scoliosis, increased intra-abdominal pressure from spasticity, seizures, or neuromuscular incoordination. Regardless of cause, chronic gastroesophageal reflux may lead to esophagitis. This may be manifested with dystonic posturing of the head and neck, hematemesis or vomiting, anemia, or chronic

irritability. Chronic peptic esophagitis may potentially cause esophageal mucosal ulceration and stricture formation. Constipation may also arise because of low-fiber or liquid diet, use of medications (including opioids, antispasmodics, antihistamines, and anticonvulsants), immobility, decreased bowel motility, hypotonia, or skeletal abnormalities. Chronic constipation may in turn lead to megarectum, anal fissures, or soiling [16,17].

Musculoskeletal

Musculoskeletal disease is the hallmark of CP. Its impact is lifelong and causes arthritic changes, deformity or contracture, and joint dislocation. This can lead to decreased mobility, osteoporosis, fracture, skin breakdown, and pain [15,17].

Pain is reported in both children and adults with CP and may be caused by muscle imbalance or spasticity. Back pain is commonly reported, followed by pain in weight-bearing joints. The presentation of CP can influence the location of pain. Foot pain is commonly reported in those with diplegic CP, whereas knee pain is more frequent in quadriplegic CP. Neck pain, shoulder pain, and headaches are reported in those with dyskinesia [17]. Pain can affect socialization and education as well as lead to fatigue and decreased mobility [18,19].

Pain affects not only mobility but also strength, endurance, balance, and spasticity. A study looking at aging with CP found that 39% of 20-year-old CP patients could ambulate 20 feet without an assistive device. This declined progressively to 37% by 40 years and 25% by 60 years of age. Subtype also played a role; spastic diplegic patients most commonly showed this progressive decline in mobility [17].

Decreased mobility can lead to osteoporosis. A study in 2008 reported that adults and children with spastic quadriplegia who are nonambulatory have decreased bone density of the lower spine across their life span [17]. Decreased mobility may also influence scoliosis progression over time. It was reported that curves of more than 4 degrees by the age of 15 years led to progressive worsening of spine curvature with age. Curvature of the spine, whether scoliosis, kyphosis, or lordosis, can affect sitting balance, increase pain, and cause difficulties with bowel and bladder management [17].

Sitting may also be influenced by hip subluxation due to muscle imbalance, especially in spastic CP [20]. Hip subluxation can lead to difficulties with wheelchair seating and fit, which may result in skin breakdown and pain, as persistent hip dislocations have been reported to increase pelvic obliquity [20].

Other joints commonly affected in CP include the knee, foot, and ankle. The most common disorders of the foot are equinus deformity, equinoplanovalgus deformity, and equinovarus deformity (Fig. 124.1). Equinus deformity is a disorder of the hindfoot characterized by excessive plantar flexion of the hindfoot in reference to the ankle. It is seen with hypertonicity of the gastrocnemius or soleus muscles. Equinoplanovalgus deformity is seen with pronation of the forefoot and midfoot and is typically accompanied by hallux valgus and valgus deformity at the ankle. This is commonly seen with increased tone to the gastrocnemius and the peroneals. Equinovarus deformity

is seen with supination of the midfoot and involves the gastrocnemius and posterior tibialis muscles [21]. Increased tone at the gastrocnemius can also produce toe walking, which is a common occurrence in CP.

Excessive knee flexion due to increased tone in the hamstrings may be seen. However, increased tone alone does not lead to the crouched gait pattern commonly seen in CP. This pattern may be due to a combination of skeletal deformity, weakness, spasticity, and poor motor control [22,23]. It is characterized by flexion at the hips, due in part to increased tone of the iliopsoas, and flexion at the knees. Increased tone of the hip adductors may lead to further gait abnormality, producing a scissoring gait pattern.

Neurologic

Neurologic symptoms are manifested across a range of body systems. This may include impairments of oral-motor control, vision deficits, and sensorineural hearing loss [15,16]. Patients may have seizures, cognitive problems, sensory impairments, weakness, movement disorders, abnormal motor control, and muscle hypertonicity.

Seizures are most commonly seen in those with spastic quadriplegia. Their presentation can vary from generalized tonic-clonic to focal, complex partial, simple partial, myoclonic, typical absence, atypical absence, or atonic. Seizures may progress to epilepsy. A study by Humphreys and coworkers [24] found an association between the development of epilepsy and the presence of neonatal seizures in CP patients with periventricular leukomalacia.

Sensory impairments can also be seen in patients with CP. Difficulties with proprioception, two-point discrimination, and stereognosis may be present. This is most common in those with the spastic hemiplegic subtype [25]. Recent literature supports these findings and notes a correlation between sensory impairment and involvement of the thalamocortical pathways [26,27].

The predominant neurologic findings in those with CP are changes in tone or movement. This is evident by the way in which CP is classified: spastic, dyskinetic (dystonic or choreoathetotic), or ataxic [1]. Spastic CP is the most common, and spasticity is its predominant feature. Spasticity is defined as hypertonia that produces increased resistance in response to increased speed of stretch. The dystonic pattern seen in dyskinetic CP is characterized by involuntary muscle contractions that can be sustained or intermittent, leading to twisting or repetitive movements or abnormal postures [28]. The choreoathetotic pattern is characterized by the combination of athetoid (slow, writhing) and choreiform (abrupt, jerky) movements. The ataxic subtype is characterized by uncoordinated movements. Hypotonia may be seen early in infancy, although it may still be present intermittently with dyskinetic CP.

Other

Sleep may be affected in those with CP as a result of sleep anxiety, night wakings, parasomnias, sleep disordered breathing, intellectual impairment leading to difficulty in self-soothing to sleep, altered light perception, reduced melatonin secretion, epilepsy, or pain. Pain may be due to restricted movement, contracture, or spasms. Wayte and

FIGURE 124.1 Common disorders of the foot.

coworkers [29] reported that persons with CP needed parental support at night most commonly for restless sleep and turning over in bed. This need for parental support led to increased caregiver burden and depression [30].

Depression has also been reported in patients with CP. It was found that adults older than 40 years with CP experienced greater levels of loneliness and depression than did 60-year-olds without a disability [17]. Depression has been associated with concern about lack of resources and expertise in care for adults with CP [31].

Physical Examination

As CP may bear influence on all body systems, it is necessary to obtain a complete history and to perform a thorough examination. It is important to consider the age of the patient and to modify the examination accordingly. Assessment should include an evaluation of function, a

detailed musculoskeletal examination (to evaluate joint range of motion, deformity, or malalignment), and a thorough neurologic examination (including evaluation of strength, tone, and sensation). Psychological and cognitive assessment may also be performed.

Mobility is classified by the Gross Motor Functional Classification System, which is divided into five categories based on independence with mobility and use of assistive devices (Table 124.1) [1,13,32–34]. Upper extremity function is categorized by the Manual Ability Classification System. This system accounts for age and primarily assesses how patients handle objects in daily life. The classification system was originally designed for those between 8 and 12 years old. It is divided into five levels with progressive involvement from level I to level V (Table 124.2). In a study by Eliasson and colleagues [35], children with hemiplegia were primarily level II, those with diplegia were either level I or level IV, and those with quadriplegia were level IV or level V.

Table 124.1 Gross Motor Functional Classification System

Level	Abilities
Level I	Children are able to walk both indoors and outdoors and climb stairs without assistance.
Level II	Children have some difficulties with mobility on uneven surfaces and hold onto a railing while climbing stairs. They are able to walk indoors and outdoors.
Level III	Children require use of an assistive device for mobility on level surfaces. This may be by walking with an assistive device or propelling a manual wheelchair.
Level IV	Children require wheeled mobility as their primary means of mobility and may walk only short distances with use of an assistive device.
Level V	Children rely on caregivers for mobility.

Table 124.2 Manual Ability Classification System

Level	Abilities
Level I	Handles objects easily, but may have difficulty with speed or accuracy
Level II	Handles most objects, but may use compensatory means to complete task
Level III	Has difficulty handling objects and requires assistance to prepare or to modify task
Level IV	Handles limited objects and requires continuous support
Level V	Does not handle objects and requires total assistance

Musculoskeletal abnormalities should be carefully evaluated as they have great impact on overall function. Signs of scoliosis should be observed. Passive and active range of motion should be assessed at all joints and may be measured with a goniometer. Specific tests can be used for the evaluation of common abnormalities (Table 124.3). Examination of the hips in infants should include assessment of hip dislocation with the Barlow and Ortolani tests. The Galeazzi or Allis sign may indicate hip dislocation or subluxation. It will be seen as an asymmetry when hips and knees are flexed to 90 degrees and the pelvis is in neutral position. It is important to assess hip abduction because increased tone to the hip adductors or hip deformity can lead to difficulties with perineal care. This is tested in the supine position, with knees flexed and hips flexed to 90 degrees, after which the hips are abducted. Internal and external rotation of the hips should be assessed. The Thomas test may be used evaluate for hip flexion contracture [36,37]. Popliteal angles should be measured with hips flexed to 90 degrees and knees initially in a flexed position, then passively extended. Ankle dorsiflexion should be measured with the knee flexed to assess tightness of the soleus and the knee extended to assess gastrocnemius tightness [37]. Deformity of the foot and ankle should also be documented. Analysis of gait in a formal gait laboratory may be useful in assessing the musculoskeletal system and mobility [34].

Neurologic examination should be appropriate for the patient's age. Primitive infantile reflexes, such as the Moro, palmar grasp, asymmetric tonic neck, plantar grasp, and

Table 124.3 Tests for Evaluation of Musculoskeletal Abnormalities

Maneuver	Purpose	Assessment
Barlow	Posterior hip dislocation	Femurs are pushed posteriorly while the hips and knees are in flexion and the thighs are in adduction. The result is positive if the maneuver produces dislocation.
Ortolani	Hip dislocation	Hips are abducted with the knees and hips flexed at 90 degrees. The result is positive if there is a palpable relocation of the hip.
Galeazzi	Hip dislocation or subluxation	Hips and knees are flexed to 90 degrees and the pelvis is in neutral position. The result is positive if there is an asymmetry.
Thomas	Hip flexion contracture	The unaffected hip and knee are passively flexed. The result is positive if this produces flexion of the affected hip.
Popliteal angle	Knee flexion contracture or tight hamstrings	Hips and knees are flexed to 90 degrees, then the knees are passively extended while the hips remain flexed.

Galant, should be provoked. The asymmetric tonic neck reflex should subside by 3 months. It is elicited by rotation of the patient's head, causing extension of extremities on the chin side and flexion on the occiput side. The Galant reflex is seen with curvature of the trunk toward the side of stimulation when the examiner scratches the skin of the patient down the back. This response should be extinguished by 4 months. The palmar grasp response, which is seen with finger flexion of the patient when the examiner's finger is placed in the palm, should disappear by 6 months. The Moro reflex, which is caused by sudden head extension and leads to upper extremity abduction, then adduction and flexion, should resolve by 6 months. The plantar grasp response is seen with flexion of the toes when the sole of the foot is touched. This should be extinguished by 15 months [38].

Muscle strength may be evaluated by observation or through formal manual muscle testing, depending on the patient's age. Developmental milestones should be discussed with parents or observed. Emergence of hand dominance at an early age should be discussed with parents as this may indicate weakness or difficulties with the nondominant hand. Variations in tone should be assessed. Spasticity may be classified by the Ashworth scale, the modified Ashworth scale, or the Tardieu rating scale. The Ashworth scale rates spasticity from 1 to 5 with increasing severity, and the modified Ashworth scale rates spasticity from 0 to 4 with increasing severity; the Tardieu rating scale measures spasticity at varying velocities [39]. Sensory examination may also be performed with assessment of proprioception, two-point discrimination, and stereognosis [25–27].

Muscle stretch reflexes should be obtained and may be increased. Formal vision and hearing assessment to ascertain visual impairment or hearing loss is often necessary. Mood should be discussed because depression is seen in those aging with CP [31]. Neuropsychological examination may be beneficial in assessment of cognitive concerns.

Functional Limitations

Functional limitations vary by subtype and comorbidities, many of which are described earlier and involve activities of daily living and mobility. It is reported that gross motor function may improve up to the age of 7 years, but musculoskeletal disease may worsen, potentially affecting mobility in children with CP [34]. Research by Palmer [40] suggests that the best predictor of functional limitation is the rate of motor development. This can be evaluated by use of the developmental quotient (chronologic age divided by developmental age) or through videotape assessment of spontaneous general movements during the first months of life [40].

Engel-Yeger and colleagues [41] reported that people with CP, compared with their typically developing peers, were more limited in their activities, were limited in the frequency of activity participation outside of school, and did not as frequently interact with peers during activities. This same article suggested that it may be the physical limitations that account for these differences.

Diagnostic Studies

Head, Eyes, Ears, Nose, and Throat

Audiometry may be obtained to assess hearing. Neuro-ophthalmology referral may be necessary for visual assessment.

Cardiovascular

With aging (if cardiac concerns arise), electrocardiography, thallium or exercise-induced stress testing, or echocardiography may be warranted.

Pulmonary

Chest radiographs may be obtained if pneumonia is suspected or there is a change in respiratory status.

Pulmonary function tests may be performed if there is concern for development of chronic obstructive pulmonary disease.

Gastrointestinal and Genitourinary

Abdominal plain films should be obtained if chronic constipation develops. Gastroenterology consultation and upper endoscopy may be necessary if there is concern for peptic esophagitis or hematemesis. If dysphagia is suspected, formal evaluation by a speech-language pathologist is warranted. This evaluation may include instrumental examination (modified barium swallow study or fiberoptic endoscopic evaluation of swallowing).

Musculoskeletal

Scoliosis films should be obtained to measure and to evaluate scoliotic curves. Hip radiographs should be ordered

when concern for congenital dysplasia or dislocation exists. Radiographs may be obtained for any suspected fracture of the limbs or vertebral compression fracture. Radiographs may also be useful in assessing degenerative changes of the peripheral joints or spine. To assess bone density, a bone density study (DEXA scan) may be ordered.

Neurologic

Initial evaluation of suspected intracranial disease in infancy may begin with cranial ultrasonography [40]. This technique is useful before cranial suture and fontanelle closure and may reveal hemorrhage, ventricular enlargement, or cystic changes. In children and adults, computed tomography may assess for hemorrhagic changes, but its use should be carefully considered, given the amount of radiation exposure. Magnetic resonance imaging is used to assess the underlying pathologic brain changes associated with the development of CP. Common findings may include hypoxic-ischemic injuries, periventricular leukomalacia, schizencephaly, and cerebellar malformations. Krageloh-Mann and Horber [42] reported that 86% of magnetic resonance images obtained in children with CP were abnormal and 83% of those gave insight into the etiology of the child's CP. There is also evidence to suggest that diffusion magnetic resonance imaging to evaluate white matter lesions, specifically looking at the corticomotor and sensorimotor tracts, is useful [26,27].

Treatment

Treatment of CP should focus on management of symptoms, maximization of function, and prevention of complications. Currently there is no cure for CP.

Initial

When treatment of CP is initiated, existing symptoms and comorbidities as well as potential complications should be considered. One such symptom may be pain, which should be addressed on the basis of etiology. If pain is due to degenerative changes, nonsteroidal anti-inflammatories may be used. Pain may arise from a trigger point and may be treated with trigger point injection. Complications from immobility, such as skin breakdown, may arise. These can be treated by off-loading of pressure but may require further interventions, such as débridement or surgical closure. Immobility can lead to pain and fatigue, for which physical or occupational therapy can be implemented. Immobility may also lead to constipation, which may require dietary modifications (increasing fiber intake), stool softeners, enemas, or other laxatives [16]. Discomfort may also arise from gastroesophageal reflux disease, for which proton pump inhibitors have been shown to be effective [16]. Depression may also arise, which may be treated pharmacologically. Referral to a psychologist or psychiatrist may also be necessary.

Rehabilitation

In establishing a treatment program, it is important to take a multidisciplinary approach with focused and clear goals in mind. Physical therapists, occupational therapists,

speech-language pathologists, and neuropsychologists may all be involved to varying degrees and at varying frequencies. Patients' goals will vary significantly and may range from independence in basic activities of daily living to assistance with management of tone, prevention of contracture, and maximizing independence with vocational or sports interests.

A wide range of interventions are available for management of abnormal tone. Assessment must be made as to whether a focal or generalized intervention is required. Physical therapy or occupational therapy may be started in either scenario to work toward implementing a home stretching program and providing education to the patient and the family on the importance of stretching. This is especially important during growth. A wide variety of orthotics may be used as well to help preserve range of motion and for functional tasks, such as providing support at the foot and ankle with mobility or support at the wrist while performing manual activities. Constraint-induced movement therapy may also be considered to promote functional use of the affected limb in those with unilateral involvement.

Generalized interventions for management of spasticity may include oral medications or intrathecal medications. Oral medications include baclofen, dantrolene, clonidine, tizanidine, and benzodiazepines. Most oral medications can have systemic effects that can affect cognition or lead to sedation. Intrathecal delivery of medication is known to have fewer systemic effects. Baclofen may be delivered through an intrathecal pump to manage spasticity [34].

Procedures

If focal intervention is needed, patients may benefit from localized procedures such as botulinum toxin or phenol injections. Botulinum toxin has been shown to be effective in reducing spasticity short term. Long-term efficacy of botulinum toxin is still unclear [34]. Botulinum toxin may be used in combination with serial casting; however, there is mixed evidence about the efficacy of this combined intervention [34].

Surgery

Surgery is an option for both focal and generalized interventions. Selective dorsal rhizotomy may be considered as a surgical treatment to help manage focal spasticity. Orthopedic surgeries to correct contracture or deformity may be necessary as well. This may include tendon lengthening (typically of the Achilles or adductors) and bone correction (such as derotational osteotomies). Generalized interventions for surgical management of spasticity may include placement of an intrathecal pump for delivery of intrathecal medications. Intrathecal delivery of medication is known to have fewer systemic effects. Baclofen may be delivered through an intrathecal pump to manage spasticity [34].

Potential Disease Complications

Because CP is a lifelong disorder, complications associated with aging are often seen. These complications may affect all body systems but predominantly include changes in tone, development of contracture, pain, weakness, decreased mobility, and depression. As described in previous sections of

this chapter, there may be increased risk of circulatory system disease, respiratory illnesses, chronic obstructive pulmonary disease, gastroesophageal reflux disease, constipation, osteoporosis, and seizures. Early-onset arthritis may also be of concern [15].

Potential Treatment Complications

Complications associated with the treatment of CP vary on the basis of the intervention. All medications have potential side effects. Oral medications, such as baclofen, dantrolene, tizanidine, and benzodiazepines, may cause varying degrees of weakness and sedation. Baclofen and benzodiazepines may lead to cognitive changes. Use of clonidine may lead to hypotension and bradycardia. Intrathecal administration of baclofen has fewer systemic effects, but other potential risks are associated with the pump and catheter. Programming errors, kinked or broken catheter, or pump malfunctioning can lead to baclofen overdose (sedation, lethargy, respiratory failure, and urinary retention) or baclofen withdrawal (cognitive changes, increased spasticity, pruritus, and seizures). Use of focal injections to treat spasticity may lead to infection at the injection site, soreness, or bleeding. Phenol may lead to dysesthesias when it is injected at the site of a mixed sensory-motor nerve. Botulinum toxin may cause weakness and in rare cases botulism-like symptoms, including difficulty in breathing and dysphagia.

Serial casting may lead to skin irritation and potential skin breakdown. Range of motion and stretching can cause pain and have the potential to cause fracture if stretching is performed too aggressively in an osteoporotic patient. Surgery, including dorsal rhizotomy and orthopedic surgeries, may have complications of postoperative pain and constipation in addition to risks of the actual procedure. There are also increased risks associated with anesthesia use when respiratory muscle compromise is present.

ICD-9 Code

780.71 Chronic fatigue syndrome

ICD-10 Code

R53.82 Chronic fatigue syndrome

Definition

Chronic fatigue syndrome (CFS) is a debilitating condition of unknown nature and cause, but most medical authorities now accept its existence. CFS is characterized by severe, disabling, medically unexplained fatigue for more than 6 months and prominently features subjective impairments in concentration, short-term memory, and sleep as well as musculoskeletal pain [1]. Sufferers experience significant disability and distress, which may be further exacerbated by a lack of understanding from others, including health professionals. CFS affects both adults and children.

Epidemiologic research in Western countries has demonstrated that among adults, between 230 and 500 of every 100,000 persons are affected with CFS [2–4]. Women have CFS more commonly [5], as do minority groups and people with lower educational status and educational attainment [2].

The causes of CFS remain uncertain. CFS may start either gradually or suddenly. In the latter case, it is often triggered by an influenza-like viral or similar illness. Some

progress in the understanding of the disease has been made when causes were divided into predisposing, triggering or precipitating, and perpetuating factors [6,7]. Personality (neuroticism, introversion) and lifestyle factors, inactivity in childhood and inactivity after infectious mononucleosis, and genetic factors are presumed to influence vulnerability in CFS. Certain infectious illnesses (e.g., Epstein-Barr virus infection, Q fever, and Lyme disease), precipitating somatic events (e.g., serious injuries), and psychological distress (e.g., serious life events) may precipitate the disorder. The perceptions, illness attributions, and beliefs of patients may encourage avoidant coping and perpetuate the illness.

Among various pathophysiologic hypotheses tested, some evidence has emerged supporting subtle hypoactivity in the hypothalamic-pituitary-adrenal axis with lower than normal cortisol response to increased corticotropin levels [8] and a hyperserotonergic state or upregulated serotonin receptors in CFS [9,10]. Whether these alterations are a cause or a consequence of CFS, however, remains unclear. Dysfunction in the immune system in CFS is inconsistently evidenced by findings of abnormal cytokine production, mainly concentrating on proinflammatory ones that are known to be involved in the regulation of the hypothalamic-pituitary-adrenal axis and sympathetic nervous system, such as tumor necrosis factor, interleukin-1, and interleukin-6 [11]. On the tissue level, cytokines such as interleukin-6 are involved in the stress response and represent crucial inducers of sickness behavior [12], which is characterized by avoidance behavior, apathy, sleepiness, impaired memory and concentration, anorexia, mild fever, and increased sensitivity to pain. No convincing evidence exists to support CFS as a continuing viral infection [11]. Increasing evidence suggests that in a large subgroup of CFS patients, central sensitization with widespread hyperalgesia, delayed diffuse noxious inhibitory control, and dysfunction of endogenous inhibition during exercise seems to corroborate several psychological influences on the illness [13]. Functional magnetic resonance imaging studies in patients with CFS revealed findings indicative of increased neuronal resource allocation [14] or dysfunctional motor planning [15], which seems to be consistent with cognitive impairment in these patients.

Symptoms

Patients with CFS typically present with a variety of symptoms that may widely overlap with symptoms of

functional somatic syndromes, including the irritable bowel syndrome, fibromyalgia, multiple chemical sensitivity, chronic pelvic pain, temporomandibular joint dysfunction, and Gulf War illness [11].

Patients experience profound, overwhelming exhaustion, both mentally and physically, which is worsened by exertion and is not completely relieved by rest [16]. Fatigue is highly subjective, multidimensional, and variable in nature, and it does not necessarily need to be the major and most debilitating symptom in this condition [1]. Patients may express their complaints of fatigue in different ways. Patients' expectations and causal attribution of symptoms to somatic factors, hidden agenda involving insurance issues, and invalidity of benefit claims have been related to an increase in symptoms and may contribute to a diversity of symptoms reported [7].

In addition to fatigue, patients with CFS usually complain about a wide variety of multisystem symptoms that are nonspecific and variable in both nature and severity over time. These may be just as prominent as fatigue and are best summarized in different categories [16,17].

- Complaints of cognitive dysfunction. CFS patients may experience forgetfulness, confusion, difficulties in thinking, and "mental fatigue" or "brain fog."
- Postexertional malaise. Patients report a period of deep fatigue and exhaustion that lasts for more than 24 hours after physical exertion.
- Complaints of pain. These include headaches of a new type, pattern, or severity; muscle pain; and multijoint pain. Patients may further report pain in bones, eyes, and testicles; abdominal and chest pain; chills; and painful skin sensitivity.
- Unrefreshing sleep and rest is a hallmark of CFS, and insomnia is also common. Patients report more difficulty in falling asleep, more interrupted sleep, and more daytime napping. It is extremely difficult for many patients to maintain a sleep schedule. Patients report that exercise, unlike in healthy persons, worsens the insomnia and unrefreshing sleep symptoms alike.
- Psychological complaints of emotional lability, anxiety, depressive mood, irritability, and sometimes a curious emotional "flattening" most likely due to exhaustion may be reported by CFS patients. CFS patients with preexisting psychiatric symptoms may report that these worsen with the onset of CFS. Treatment of psychiatric symptoms alone does not relieve the physical symptoms of CFS, indicating that the disease is not only psychological in nature.
- Other frequently reported complaints refer to general hypersensitivity and poor temperature control; these include low-grade fevers, photophobia, vertigo, nausea, allergies, hot flashes, and rashes [18,19].

Physical Examination

The physical examination is directed toward determination of whether symptoms are caused by any other disease or illness. The findings of the general medical and neurologic examinations should be normal. There may be low-grade fever with temperatures between 37.5°C and 38.5°C orally, nonexudative pharyngitis, and tender cervical or axillary lymph nodes up to 2 cm in diameter. A mild hypotension,

elicited mainly with tilt-table testing and reversed by mineralocorticoids, may be observed. In some patients, orthostatic hypotension with wide swings in blood pressure resulting in syncope as well as intermittent hypertension may be found [20]. Complaints of paresthesias usually prove to be odd on sensory testing, particularly numbness in the bones or muscles or fluctuating patches of numbness or paresthesias on the chest, face, or nose. A few patients report blurred or "close to" double vision. In neither case are there physical findings to corroborate the sensory experiences [20]. Unsteadiness on standing with closed eyes may be found.

A thorough mental status examination is performed to rule out any exclusionary psychiatric disorders. The psychological examination may reveal abnormalities in mood, intellectual function, memory, concentration, and personality. Particular attention should be paid to anxiety, self-destructive thoughts, and observable signs such as psychomotor retardation [1].

The musculoskeletal examination findings should be normal. In CFS patients with arthralgia and myalgia, joint swelling and inflammation and other superimposed pain generators, such as bursitis, tendinitis, and radiculopathy, have to be ruled out. Palpatory examination of muscles may reveal tender muscles, tender points that are not numerous enough to be classified as fibromyalgia, and individual trigger points.

Functional Limitations

Disablement varies widely among patients with CFS. Whereas some are able to lead a relatively normal life, others are totally bed bound and unable to care for themselves. In a rehabilitative assessment, body functions that represent the patient's core subjective symptoms may reveal the most pronounced impairment; these are energy and drive functions, sensation of pain, sleep functions, attention function, emotional functions, memory functions, and exercise tolerance functions. Both muscle and cardiopulmonary function as demonstrated by cardiopulmonary stress testing may be reduced in these patients. Avoidance behavior as a consequence of patients' experiencing worsening of symptoms after previously well-tolerated levels of exercise and kinesiophobia—a specific kind of fear-avoidance behavior that is defined as an excessive, irrational, and debilitating fear of physical movement and activity resulting from a feeling of vulnerability to painful injury or reinjury—may increase sedentariness in CFS patients. However, kinesiophobia was not correlated with reduced exercise capacity by bicycle ergometer exercise stress testing [21].

CFS patients may be able to begin but not to complete mental or physical activities that were previously easily accomplished. Thus, tasks that predominantly challenge the cognitive performance, like focusing attention, solving problems, handling stress, making decisions, undertaking multiple tasks, or driving a car, may limit patients in carrying out their daily routine, especially at the workplace. Tasks that require predominantly physical performance, like walking or household tasks, may limit the patient's activities of daily life. Many patients have to modify or give up physical hobbies and exercise and find themselves

Table 125.1 Case Definition (1994) for Chronic Fatigue Syndrome from the U.S. Centers for Disease Control and Prevention

Characterized by Persistent or Relapsing Unexplained Chronic Fatigue

Fatigue lasts for at least 6 months
Fatigue is of new or definite onset
Fatigue is not the result of an organic disease or of continuing exertion
Fatigue is not alleviated by rest
Fatigue results in a substantial reduction in previous occupational, educational, social, and personal activities
Four or more of the following symptoms, concurrently present for ≥ 6 months: impaired memory or concentration, sore throat, tender cervical or axillary lymph nodes, muscle pain, pain in several joints, new headaches, unrefreshing sleep, or malaise after exertion

Exclusion Criteria

Medical condition explaining fatigue
Major depressive disorder (psychotic features) or bipolar disorder
Schizophrenia, dementia, or delusional disorder
Anorexia nervosa, bulimia nervosa
Alcohol or substance abuse
Severe obesity

Modified from Fukuda K, Straus SE, Hickie I, et al; International Chronic Fatigue Syndrome Study Group. The chronic fatigue syndrome: a comprehensive approach to its definition and study. *Ann Intern Med* 1994;121:953-959; and Prins JB, van der Meer JW, Bleijenberg G. Chronic fatigue syndrome. *Lancet* 2006;367:346-355.

Table 125.2 Laboratory Tests Recommended for the Exclusion of Diseases That May Cause Chronic Fatigue

Complete blood count with differential cell count
Blood and serum chemistries (serum electrolytes, blood urea nitrogen, glucose, creatinine, calcium)
Erythrocyte sedimentation rate
Urinalysis
Thyroid function studies
Antinuclear antibodies
Serum cortisol concentration
Immunoglobulin levels
Rheumatoid factor
Tuberculin skin test
Human immunodeficiency virus serology
Lyme serology (when endemic)
Magnetic resonance imaging of head (to rule out multiple sclerosis)
Polysomnography (to rule out sleep disorder)

Optional Tests to be Used When Clinically Indicated

Quantification of natural killer cells
Quantification of B- and T-cell subsets
Functional elevation of natural killer cells
T-cell response to mitogenic stimulation
Measurements of delayed hypersensitivity
Production of and response to cytokines
Enzyme-linked immunosorbent assay/activated cell test
Serologic tests for *Candida albicans*
RNase L enzymatic activity assay or RNase L protein quantification
Spinal tap for oligoclonal bands
Tilt table
Catecholamine testing
Nerve conduction studies including electromyography
Anti-acetylcholine receptor antibodies
Vitamin B₁₂ deficiency
Circulating immune complexes including CD3 and CD4
Viral serologies

Modified from Craig T, Kakumanu S. Chronic fatigue syndrome: evaluation and treatment. *Am Fam Physician* 2002;65:1083-1090; and Wikipedia 2007/results from an NIH consensus conference.

unable to work full-time or at all [17]. Categories related to intimate relationships, family relationships, communication, and complex interpersonal relationships may be altered in CFS patients, thereby restricting them from participation in social and work life.

Cognitive avoidance coping as a major illness-perpetuating factor was found negatively related to social functioning [22], and a strong association seems to exist between kinesiophobia and self-reported activity limitations and participation restrictions in CFS patients [21]. In addition to environmental factors related to the immediate family and friends, health professionals may reinforce patients' symptom severity and illness behavior and facilitate further impaired functioning in these patients. Personal beliefs, practices, ideologies, spirituality, laws, and societal norms may also facilitate or hinder functioning in CFS patients. A considerable number of patients with CFS in many countries are receiving disability benefits or private insurance or have made claims and been denied [23].

Diagnostic Studies

There are no accepted diagnostic tests for CFS. Diagnosis of CFS is primarily based on the patient's symptoms that fit scientific case definitions of CFS, which aim to effectively distinguish CFS from other types of unexplained fatigue. Among numerous scientific case definitions available, the U.S. Centers for Disease Control and Prevention criteria are the most widely supported [1]. This case definition characterizes CFS by a grouping of nonspecific symptoms and a diagnosis of exclusion (Table 125.1). To receive a diagnosis of CFS, fatigue must have persisted or recurred during 6 or more consecutive months. Concomitant symptoms must have persisted or recurred during 6 or more consecutive months of illness and cannot have predated the fatigue [16]. Clinicians may have difficulties in diagnosis of CFS, especially by not acknowledging the diagnosis of fatigue when its onset is gradual or by the diversity of patients' fatigue reports. Instruments developed to assess fatigue, such as the Checklist Individual Strength, the Chalder Fatigue Scale, and the Krupp Fatigue Severity Scale, are widely used in research studies and may assist physicians with objectivation of fatigue and establishment of the medical diagnosis.

Fatigue and similar symptoms can be caused by a wide variety of conditions. Thus, diagnosis of CFS needs to include a diagnostic process that eliminates potential causes of the patient's symptoms (see the section on differential diagnosis). In addition to a thorough history and a meticulous physical examination, diagnostic studies include a mental status examination and a minimum array of laboratory tests.

A structural psychiatric interview is essential to identify permanent psychiatric exclusions (see Table 125.1 and the section on differential diagnosis). Reliable detection instruments may be helpful when physicians perform screening for psychiatric diagnoses, such as the Composite International Diagnostic Interview [24] and the Structured Clinical Interview for DSM-IV Axis I (SCID) [25].

Laboratory examination is intended to detect other disorders, not to find out whether a patient has CFS. Recommendations for laboratory testing have been provided (Table 125.2).

Questionnaires such as the Epworth Sleepiness Scale and the Centre for Sleep and Chronobiology Sleep Assessment Questionnaire are useful to screen for and to profile sleep abnormalities [26]. Polysomnography defines sleep architecture, duration and timing of sleep, respiratory obstruction, and abnormal limb movements and may be indicated when primary sleep disorders exclusionary to CFS, such as sleep apnea and narcolepsy, have to be ruled out.

Assessment of a patient's functioning and health according to the International Classification of Functioning, Disability, and Health (ICF) [27] would further complete the diagnostic studies in patients with CFS. The classification might be recommended, but compared with other chronic conditions like osteoarthritis and back pain, ICF core sets that best describe the prototypical spectrum of disability have not yet been developed for CFS [28,29]. Furthermore, ICF core sets have to be psychometrically validated after they have been developed. This can be best accomplished by item response theory-based computerized adaptive testing, a method selecting only those items out of the item pool that are most relevant for the individual patient [30,31]. For the time being, instruments that have been recommended in a consensus conference may be used to measure the symptom-specific disablement and quality of life of patients with CFS [16].

Differential Diagnosis [32,33]

Blood

- Anemia
- Hemochromatosis

Infections

- Chronic Epstein-Barr virus infection
- Influenza
- Hepatitis
- Human immunodeficiency virus infection
- Lyme disease
- Occult abscess
- Poliomyelitis, postpoliomyelitis syndrome
- Tuberculosis
- Bacterial endocarditis
- Chronic brucellosis

Parasites

Fungi

Autoimmune disease

- Behçet syndrome
- Dermatomyositis
- Lupus erythematosus
- Polyarteritis
- Polymyositis
- Reiter syndrome
- Rheumatoid arthritis
- Sjögren syndrome
- Vasculitis

Liver disease

Chronic heart disease

Chronic lung disease

Metabolic and toxic conditions

Endocrine disease

- Diabetes mellitus
- Hyperthyroidism and hypothyroidism
- Addison disease
- Cushing syndrome
- Panhypopituitarism

Ovarian failure

Malignant neoplasms

Neuromuscular disorders

Fibromyalgia

Multiple sclerosis

Parkinson disease

Myasthenia gravis

Head injuries

Sleep disorders

Obstructive sleep syndromes (sleep apnea, narcolepsy)

Psychiatric

Bipolar affective disorders

Schizophrenia of any subtype

Delusional disorders of any subtype

Dementias of any subtype

Organic brain disorders and alcohol or substance abuse within 2 years before onset of the fatiguing illness

Other

Pharmacologic side effects

Alcohol and substance abuse

Body weight fluctuation (severe obesity or marked weight loss)

Treatment

Initial

Treatment of CFS is symptom based and aims to improve fatigue and comorbid conditions, such as sleep disturbances, depression, and painful symptoms.

Treatment of CFS with pharmacologic therapies has had disappointing results in most cases. So far, no pharmacologic treatments have been proved effective in the treatment of fatigue. The subtle changes found in the hypothalamic-pituitary-adrenal axis have led to a few randomized controlled trials that overall did not establish steroids as a treatment of choice [34]. For immunologic therapies like immunoglobulin G, staphylococcus toxoid, ribonucleic acid, and others, there is insufficient evidence about their effectiveness in CFS [34].

Anecdotal evidence suggests that low doses of anti-depressant medication (e.g., 10 to 30mg of nortriptyline) administered at bedtime improve sleep and diminish pain, although the benefit of these medications has not been demonstrated in CFS [34,35]. In addition, the use of acetaminophen, nonsteroidal anti-inflammatory drugs, and opioids may be worthwhile in patients with prominent musculoskeletal complaints or headaches.

Complementary medicine has gained increasing popularity among patients with chronic diseases. These treatments include homeopathy, herbal remedies, supplements, megavitamins, special diets, and energy healing. Although individual studies revealed beneficial effects for homeopathy and supplements in the treatment of CFS, there is insufficient evidence for the effectiveness of these interventions [34].

Rehabilitation

Management based on a rehabilitation model is now recommended for patients with CFS. The individual rehabilitative assessment is necessary to identify those treatment targets that are most likely to reach the rehabilitation aims of the patient with CFS. These

rehabilitation programs may involve different professions and therapies, and increasing evidence for the effectiveness of individual rehabilitation interventions has emerged [34–37].

Cognitive-behavioral therapy for CFS addresses changing of condition-related cognitions and behaviors and incorporates two elements: (1) a cognitive element focusing on the modification of thoughts and beliefs thought relevant for the disease process and (2) a behavioral element consisting of a graded increase of activity. Several systematic reviews suggest that cognitive-behavioral therapy for adults with CFS is an effective treatment in improving both physical functioning and symptoms such as fatigue, anxiety, and mood compared with either routine care or relaxation therapy [34–36]. Furthermore, one study provided evidence supporting the effectiveness of cognitive-behavioral therapy in children and adolescents [38]. In this study, cognitive-behavioral therapy was associated with a significant positive effect on fatigue, symptoms, physical functioning, and school attendance.

Graded exercise is designed to overcome deconditioning and to increase strength and cardiovascular health. Cycle ergometer training, swimming, or walking may be combined according to the patient's preferences. Graded exercise has no intentions of explicitly treating cognition but should incorporate considerable education wherein the sufferer learns to start at an appropriate level of activity (based on intensity and duration) that is gradually increased, at a rate that does not substantially increase symptoms. If severe fatigue follows exercise, lasting more than 24 hours, the exercise prescription is adjusted so it is less demanding; there are no specific and firm guidelines because of the wide spectrum found in this syndrome. Overall results from systematic reviews suggest that graded aerobic exercise therapy, at intensities between 40% and 70% of the maximum oxygen consumption performed three to five times per week for 30 minutes, is a promising intervention with positive effects on CFS patients' symptoms and quality of life [34,37]. Compared with the symptom-oriented approach of exercise therapy, the time-contingent approach, which considers the duration and frequency of exercise therapy to reverse deconditioning (and in which exercise intensity is based on achievable exercise at baseline, followed by a negotiated gradual increase) [39], seems to clearly offer more advantages in symptom reduction and improving functioning [40]. A few patients may find health benefits and pain relief from other than aerobic exercises, like gentle stretching and gentle strengthening including yoga or Tai Chi.

Education of the individual as to what is known and not known about CFS, its impact on function at work and home, and its prognosis should be included in the rehabilitation programs. Education of patients in self-management strategies that consider when, how, and why people change their behavior over time (transtheoretical model) [41] is of utmost importance in modern rehabilitation. The transtheoretical model describes a "meta" model and critically incorporates aspects of other models into its theoretical framework. These are self-initiated and professionally facilitated changes in health beliefs, behavioral intentions, decision-making processes, self-efficacy, and coping to overcome the temptations

component of the transtheoretical model. Patients are better prepared for coping on a daily basis, have more realistic expectations, and think that the physician is not ignoring their concerns. In addition, when appropriate, the individual should be informed that periodic reassessment for a possible treatable underlying process may ensue. This may help relieve anxiety about abandonment. Avoidance of heavy meals, alcohol, caffeine, and total rest can help, as can minimizing intake of substances that alter sleep patterns or alter one's self-image [42].

Procedures

Treatment is symptomatic; therefore, procedures may be chosen to help with trigger points, dizziness, headache, or other symptoms as they occur. If trigger points are noted, appropriate therapy may be initiated. Spray and stretch techniques, dry needling, and trigger point injection with a local anesthetic or small amount of steroid have all met with some success [43].

Acupuncture is an important constituent of traditional Chinese medicine. It is believed in traditional Chinese medicine that acupuncture can strengthen the vital essence of the human body and remove the blockage in energy channels. The application of acupuncture for CFS is mainly empirically based; a few clinical trials that included a control group suggest that this procedure may be effective in reducing symptoms [44].

Surgery

No specific surgery is performed for CFS.

Potential Disease Complications

Recovery without treatment is rare, with a median recovery rate of 5% and improvement rate of 39.5% [5]. Recovery episodes seem more likely in patients with less severe fatigue and if patients do not attribute the illness to physical causes [5]. The primary complication of the disease is continued fatigue and loss of function, which commonly occur despite treatment. Predictors of poor treatment outcome were membership in a self-help group, receipt of a sickness benefit, claiming of a disability-related benefit, low sense of control, strong focus on symptoms, and pervasively passive activity pattern [7].

Both reduced functioning and sedentariness may increase the progress or severity of chronic diseases of the cardiovascular and metabolic systems, thereby further increasing the disablement of patients with CFS.

Potential Treatment Complications

Physicians who convey understanding and compassion to patients, despite the lack of a known "cure," can alter a patient's quality of life; fear, or the perception of being abandoned, can markedly accentuate frustration and accelerate a decline in function. Medication side effects should be reviewed on an intermittent basis to be certain that the nonspecific symptoms found in CFS are not being accentuated. Care should be taken to avoid too strenuous an exercise program because the fatigue that may ensue can be

both physically and mentally debilitating. Despite optimal care, depression, fatigue, and a loss of function may still occur. Physicians and patients should both be aware that symptoms found in CFS may persist for months or years but that remittance or recovery is still possible.

Acknowledgment

The author thanks Dr. Thomas Brockow, FBK German Institute for Health Care Research, for his valuable comments on the manuscript.

Synonyms

Arthrofibrosis
Capsulitis
Ankylosis

ICD-9 Codes

M24.5 Contracture of joint
M24.6 Ankylosis of joint
M96.0 Arthrodesis

ICD-10 Codes

M24.50 Contracture, unspecified joint
M24.60 Ankylosis, unspecified joint
Z98.1 Arthrodesis status

Definition

A joint contracture is a limitation in the passive range of motion of a joint. Changes in articular structures (bone, cartilage, capsule) or nonarticular structures (muscles, tendons, skin) can prevent a joint from moving passively through its full range. A classification according to the tissue limiting the range of motion is proposed in [Table 126.1](#).

By this definition, regardless of the nature of the tissue alteration, if it results in joint motion limitation, the joint condition is called a joint contracture. For example, a muscle with adaptive shortening or fibrosis restricting joint motion is classified as joint contracture—myogenic type. It should not be referred to as a muscle contracture.

As such, joint motion limited by pain or spasticity qualifies as a joint contracture only if the limitation is demonstrated after the pain or the influence of the hyperactive upper motor neuron (increased tone, spasticity, co-contraction) has been removed. For example, when a person with a spinal cord injury is treated for spasticity, the tone in the lower

extremities will be reduced and an apparent chronic ankle plantar flexion contracture may disappear.

Conventionally, a joint contracture is named according to the joint involved and the direction *opposite* the lack of range. Some examples: a knee flexion contracture lacks full extension; an elbow extension contracture lacks full flexion; and an ankle plantar flexion contracture lacks dorsiflexion.

A contracture is the final common path of numerous conditions preventing movement of a joint through its full range of motion. Pain, trauma, immobility, weakness, and edema commonly contribute to reduced joint range of motion. The body's natural reaction to a painful joint is to "splint" or immobilize it. Not moving the joint through its full range, with time, can cause structural changes to one or more articular or nonarticular tissues, and a joint contracture can ensue [1]. Joints traumatized by fracture or reconstructive surgery, such as anterior cruciate ligament repair or arthroplasty, are susceptible to contractures [2]. Joint contractures can happen as a consequence of the disease (prolonged immobility in bed in intensive care units; [Fig. 126.1](#)) or as part of the treatment (casting after fracture or prolonged use of a brace). Any joint can be affected. At the spine, affected vertebral amphiarthrodial and facet diarthrodial joints can limit the range at one or more segments.

Neurologic conditions that increase muscle tone or cause weakness contribute to contractures because of unequal forces generated by opposing muscle groups. In upper motor neuron conditions, such as after a stroke or traumatic brain injury, spasticity and excessive muscle tone prevent a joint from accessing portions of its normal range [3]. Similarly, in lower motor neuron injuries, such as a plexopathy or peripheral nerve injury, the unopposed muscle pull will limit joint motion toward the paralyzed muscle. The range of motion not accessed will eventually be lost, resulting in a joint contracture.

A number of other local conditions, such as arthritis, joint infections, and burns, will cause contractures [4]. In addition, conditions affecting multiple systems, such as muscular dystrophy, diabetes, and Parkinson and Alzheimer diseases, can limit mobility or initiation and put the patient at risk for contractures.

Data on incidence and prevalence of joint contractures are limited and often describe one specific joint [4]. Nevertheless, these studies indicate a common problem. At least one joint contracture was noted in 7% to 51% of

Table 126.1 Classification of Contractures According to the Tissue Restricting the Range of Motion of the Joint

Type	Condition*
Arthrogenic	
Bone	Intra-articular fracture, osteophyte
Cartilage	Osteochondritis dissecans
Synovium	Pigmented villonodular synovitis, synovial chondromatosis
Capsular	Secondary to immobility and capsular shortening, adhesive capsulitis, arthrofibrosis
Other	Meniscal tear, labrum tear, palmar or plantar fibromatosis
Myogenic	
Muscle	Muscle fibrosis, myositis ossificans, muscle adaptation to altered neurologic supply (spasticity, flaccidity)
Fascia	Eosinophilic fasciitis
Tendinous	Tendon transposition, shortening
Cutaneous	Burn, scleroderma
Mixed (any combination of the above types)	Burn and adhesive capsulitis

*One or more clinical conditions illustrate each type of joint contracture.

persons after a spinal cord injury [5–7]. Between 16% and 81% of persons with an acquired brain injury developed a joint contracture [3,8,9], and 51% of children who had an obstetric brachial plexus injury were found to have a shoulder contracture [10]. In institutionalized elderly, one study reported that 71% of those who were immobile had a joint contracture, whereas none of the mobile patients had a joint contracture [11].

Symptoms

Joint contractures develop insidiously and may progress asymptotically. They are painful only with attempts to move the joint through its full range beyond the restriction. Many daily activities do not require a joint to move through its entire range. Therefore a contracture may develop unnoticed for extended periods until the joint restriction

Table 126.2 Range of Motion Required to Perform Select Activities of Daily Living

Activity	Joint	Required Range
Walking	Knee	60° of flexion [12]
	Ankle	15° of dorsiflexion [13] 20° of plantar flexion [13]
Ascending stairs	Knee	94° of flexion [14]
	Hip	67° of flexion [14]
Eating (fork to mouth)	Elbow	128° of flexion [15]
Combing hair	Shoulder	105° of abduction [12] 90° of external rotation [12]
Perineal hygiene	Shoulder	90° of internal rotation [12]
	Wrist	54° of flexion [16]
Open a door with doorknob	Elbow	35° of pronation [15] 23° of supination [15]
	Wrist	32° of ulnar deviation [16]
Open and close jar lid	Wrist	10° of radial deviation [16] 36° of ulnar deviation [16]

interferes with functional activity (Table 126.2). In the outpatient setting, patients with hand and finger joint contractures might present with complaints of a weak or ineffective grasp. A patient with a knee flexion contracture may complain of a limp [17] or of hip or low back pain. Nearly half of tetraplegic spinal cord injury patients with a shoulder contracture experienced shoulder pain [18]. Subjects with spinal muscular atrophy or congenital myopathy were more than eight times more likely to experience elbow pain if they had an elbow contracture [19].

Physical Examination

The patient must be relaxed, properly positioned, and in no pain. The clinician inspects the patient for abnormalities of limb shape, size, symmetry, and position. Edema, effusion, or deformity of the joints is noted. Skin is also assessed for any areas of breakdown or thickening complicating a contracture. Palpation of joints for swelling and tenderness must be completed. Passive range of motion is particularly important when weakness prevents normal active movement. The most precise tool for joint

FIGURE 126.1 Prolonged bed rest is a risk factor for contractures in multiple joints.

FIGURE 126.2 Example of how to measure a joint with a universal goniometer. (Modified from Norkin CC, White DJ. *Measurement of Joint Motion: A Guide to Goniometry*, 3rd ed. Philadelphia, FA Davis, 2003.)

measurement is a universal goniometer (Fig. 126.2). Spine combined movements can be assessed with an inclinometer. Comparison is made with the contralateral side or with normative values [20].

A complete neuromuscular examination can detect potential causes of contractures. Particular attention must be paid to strength and specifically to the presence of muscle imbalance in opposing muscle groups. Reflexes and tone are assessed. In the presence of spasticity, the clinician should first apply prolonged passive stretch to determine whether a full range of motion can be achieved. If it is not achieved, the clinician can use modalities (e.g., therapeutic heating), optimize medication, or use motor block injections to rule out that spasticity is masking normal passive range of the joint. Finally, a sensory examination detecting abnormal sensation will influence the choice of treatment modalities.

Functional Limitations

Joint contractures affect the performance of activities of daily living. Functional limitations depend on the underlying medical condition, the joints affected, and the severity of the joint contractures (Table 126.2). Upper extremity contractures of the elbow, wrist, and fingers impair the performance of all basic activities of daily living, such as dressing and grooming, as well as advanced skills requiring fine motor coordination, like writing. In a disabled elderly population, half as many subjects with an upper limb contracture fed themselves compared with those without a contracture [21]. Upper limb contractures can also limit mobility in patients using gait aids. Lower extremity contractures interfere mainly with mobility [21]. Hip and knee flexion contractures alter gait pattern, increase energy expenditure, and impair wheelchair mobility and car transfers. Fixed spinal deformity may limit many activities of daily living. Patients with transtibial amputations are at risk for development of a knee flexion contracture after their amputation (Fig. 126.3A). This may result in an inability to fit that patient with the most functional below-knee prosthesis. Instead, a bent-knee prosthesis, offering the patient less function and increased energy cost, must be used (Fig. 126.3B). Multiple upper and lower limb joint contractures exacerbate disability.

Diagnostic Studies

The diagnosis of a joint contracture is clinical. Radiographic evaluation can identify contributing conditions, such as osteophytes and heterotopic ossification. If a systemic cause is suspected, specific investigations are indicated.

FIGURE 126.3 A, Knee flexion contracture in a below-knee (transtibial) amputee. B, Example of a bent-knee prosthesis.

Differential Diagnosis

Spasticity
Heterotopic ossification
Degenerative joint disease
Fracture
Dislocation
Loose body in a joint
Meniscal tears
Psychogenic

Treatment

Initial

Successfully treating a medical condition that limits the joint range of motion may resolve the contracture; however, such conditions can also produce an irreversible joint contracture. A stepwise assessment and treatment plan may therefore be needed.

Prevention is at the heart of joint contracture management. Moving joints actively or passively through their full range on a daily basis prevents contractures. Continuous passive motion devices, such as those used after total knee joint arthroplasty, can achieve this postoperatively [22].

Pain control is essential to the prevention and treatment of contractures, particularly after an acute injury or after a surgical procedure [23]. Rest, ice, compression, elevation, and joint protection can help reduce pain in the acute stage, allowing earlier initiation of range of motion. Appropriate use of analgesics will promote the patient's comfort and compliance with stretching sessions.

Therapeutic positioning and splinting prevent contractures in immobilized patients [23]. These measures maintain the correct length of connective tissue and alternate between different positions of the joint. An example of therapeutic positioning is lying prone to stretch the hip joints in extension. External rotation and abduction of the shoulders with an arm support attached to the bed of patients in the intensive care unit will maintain shoulder range. Standing upright or on an incline will help stretch the ankle joints. Hand and finger as well as ankle static orthoses are useful for preventing finger and ankle contractures.

Rehabilitation

Once contractures have developed, rehabilitation includes sustained stretching and exercises to increase range of motion. Again, analgesia and control of spasticity should be optimized to benefit the stretching sessions. A recent Cochrane review has questioned the effectiveness of up to 7 months of stretching in the treatment of contracture in both neurologic and non-neurologic conditions [24]; therefore, aggressive treatment may be required during a longer period.

Therapeutic modalities are commonly used to potentiate the effect of stretching sessions. The combination of modalities that heat soft tissues with stretching is an effective treatment [25]. Ultrasound, for example, heats soft tissues around large joints to a therapeutic temperature range of 40° C to 43° C, improving their elasticity [23]. Small joints can be heated by the use of paraffin bath dips or hydrotherapy (e.g., for hand and finger contractures in scleroderma or nerve injury).

Dynamic bracing can achieve prolonged, continuous stretching of joint contractures. Serial casting or serial splinting is also used with the same intent. After maximal stretching, a cast or orthosis is applied to preserve gains. The cast or orthosis is removed every 2 or 3 days, stretching is repeated, and the cast or orthosis is reapplied at an enhanced angle (Fig. 126.4). Joints casted or splinted at the end range of motion for longer periods led to improved benefit [26]. Serial casting or splinting should be carefully monitored on limbs with circulatory or sensory compromise because of increased risk of skin breakdown and ulcer formation.

Provision of assistive devices to lessen specific disability and of gait aids to try to normalize gait completes the rehabilitation process.

Procedures

If spasticity is thought to maintain contractures, despite optimized oral medication, treatments such as motor point blocks with phenol or botulinum toxin injections or intra-thecal baclofen are considered. These procedures can be diagnostic as well as therapeutic because they can differentiate a joint contracture from spasticity. These procedures

FIGURE 126.4 Serial short leg casts depicting a reduction of plantar flexion contracture of 20 degrees to a final holding cast at 5 degrees of dorsiflexion. Several intermediate casts between the initial and final holding casts may be required to achieve gradual dorsiflexion range.

can constitute an adjunct to dynamic bracing and serial casting or splinting.

Extracorporeal shock wave lithotripsy [27] and ablative laser therapy [28] are being evaluated for skin-related contractures.

Surgery

In fixed contractures, surgical treatments include tenotomy, tendon lengthening, joint capsule release, and joint reconstruction. In some cases, skin grafts or flaps may be necessary to close resulting large skin defects [29]. These procedures are reserved for patients in whom less aggressive methods of treatment have failed and the fixed contractures significantly affect function [23].

Potential Disease Complications

Joint contracture can lead to ankylosis of a joint with corresponding loss of function. Upper limb contractures, especially if they are affecting multiple joints, can lead to dependency for all aspects of care. Mobility can be decreased to a bedridden state. Pressure sores can develop because of the limited options for mobility and weight-bearing areas. Infection by bacterial and fungal agents can occur in the skinfolds if contractures prevent adequate access for hygiene.

Potential Treatment Complications

Aggressive stretching can inadvertently result in pain; tears in muscle, ligament, or capsule; and joint subluxation. These complications can lead to bleeding, especially in patients receiving anticoagulation or those with a bleeding diathesis or thrombopenia.

Splinting and casting can result in skin ulceration or limb ischemia if patients are inappropriately selected or not closely monitored. This risk is increased if the patient lacks protective sensation because of the underlying disease.

I80.209 Phlebitis and thrombophlebitis of unspecified deep vessels of unspecified lower extremity

Definition

Venous thromboembolism is a major cause of mortality and morbidity and is manifested by deep venous thrombosis (DVT) and pulmonary embolism. This chapter is limited to the discussion of DVT. DVT occurs when a fibrin clot abnormally occludes a vein in the deep venous system, predominantly in the lower extremities. The prevailing theory explaining the development of DVT is known as Virchow triad, which includes alterations in blood flow (stasis), vascular endothelial injury, and hypercoagulation

disorder. The risk for development of DVT varies according to specific characteristics of the patient, the medical condition, or the surgical procedure (Table 127.1). Conditions that may increase the risk for development of DVT are advanced age, morbid obesity, varicose veins, prolonged immobility, pregnancy, malignant disease, stroke, inflammatory bowel disease, congestive heart failure, and previous DVT. Certain hereditary conditions may also predispose to development of DVT, such as deficiencies in protein C and protein S and familial thrombophilia. Acquired deficiencies of the natural anticoagulant system include antibodies directed against antiphospholipid and heterozygous factor V Leiden mutations [1].

Patients can be categorized according to their risk for development of DVT [2] on the basis of the type of surgical procedure; orthopedic patients carry the highest risk [3] (Table 127.2). It is believed that orthopedic procedures carry such a high risk for DVT because the mechanical destruction of bone marrow during most orthopedic procedures causes intravasation of marrow cells and cell fragments and elevations of plasma tissue factor [4]. Plasma tissue factor is a potent trigger of blood clotting [5] and is found in high concentrations in bone marrow and the adventitia surrounding the major blood vessels and the brain, which places neurosurgical patients at great risk for development of DVT. After neurosurgery, the incidence of DVT has been reported to be as high as 50% [6]. Risk factors that increase the rates of DVT in neurosurgery patients include intracranial surgery, malignant tumors, duration of the surgery, and presence of paresis or paralysis of the lower limbs [7]. Patients can remain in a hypercoagulable state up to 5 weeks postoperatively [8]. In addition to surgical patients, victims of orthopedic and neurologic trauma are at great risk for development of DVT, especially if long bone fracture or paralysis is sustained. Patients who suffer injury to the spinal cord are at high risk for DVT because of stasis and hypercoagulability.

Symptoms

Venous thrombosis often occurs asymptotically. Symptoms of DVT may include ipsilateral lower extremity edema, fever, extremity warmth, and pain. Symptoms do not rule in or rule out DVT but can serve only as a trigger for further diagnostic inquiry.

Table 127.1 Risk Factors for Deep Venous Thrombosis

Patient Factors	Diseases	Procedures
Age >40 years	Thrombophilia	Pelvic surgery
Obesity	Antithrombin	Lower limb
Varicose veins	III, protein	orthopedic
Prolonged immobilization	C, protein S deficiency	surgery
Pregnancy	Antiphospholipid antibody, lupus anticoagulant	Neurosurgery
High-dose estrogen therapy	Malignant disease	
Tamoxifen	Major medical illness	
Bevacizumab	Trauma	
Previous deep venous thrombosis	Spinal cord injury	
	Paralysis	

Modified from Sokolof J, Knight R. Deep venous thrombosis. In Frontera WR, Silver JK, Rizzo TD Jr, eds. *Essentials of Physical Medicine and Rehabilitation*, 2nd ed. Philadelphia, WB Saunders, 2008.

Physical Examination

The classic signs of DVT are tenderness, ipsilateral swelling, and warmth. A palpable cord can sometimes be felt, which reflects a thrombosed vein. In the past, emphasis was placed on the presence of Homan sign and calf tenderness in making a clinical diagnosis of DVT; however, these physical examination findings have been found to be nonspecific with poor positive predictive values [9]. Significant asymmetric calf edema is an important sign and can be determined by taking the circumferential measurement of the calf 10 cm below the tibial tuberosity. A 3-cm difference in calf girth is considered a significant clinical difference. When it is massive, the swelling can obstruct not only venous outflow but arterial inflow, leading to phlegmasia cerulea dolens due to ischemia. Here, the leg is usually blue and painful.

Like symptoms, physical examination findings are not sensitive or specific. In more than 50% of the instances of DVT, physical examination findings are normal.

Functional Limitations

DVT rarely causes functional compromise, except calf pain during walking. Absolute bed rest is generally not indicated, and early walking is safe in patients with acute DVT and may help reduce acute symptoms [10]. However, patients should suspend their lower extremity exercise program until they are fully anticoagulated.

Diagnostic Studies

The Wells prediction rules (Table 127.3) are a group of clinical characteristics that are useful in estimating the pretest probability of DVT. High-quality evidence exists to support the validity of these rules, and their use is recommended as a practice guideline by the American Academy of Family Physicians and the American College of Physicians [11]. They are easily implemented before more definitive testing is performed on patients [12].

Invasive and noninvasive diagnostic tests are available to screen for DVT. These include contrast venography, compression ultrasonography, impedance plethysmography, D-dimer testing, and magnetic resonance venography.

Contrast venography is an invasive test that is considered the “gold standard” for the diagnosis of DVT and is the only test that can reliably detect DVT isolated to the calf veins, the iliac veins, and the inferior vena cava (Figs. 127.1 and 127.2). The drawbacks to venography are its technical complexity, the requirement for the use of contrast media, the risk of allergic reaction, and the patient’s discomfort. Therefore it is not recommended as an initial screening test.

Compression ultrasonography (real-time, B-mode venous) is the procedure of choice for the investigation of patients with suspected DVT. Venous ultrasonography allows direct visualization of the vein lumen. The inability to compress the lumen of the vein is the main criterion for a positive test result. Other adjunctive findings include vein distention, absence of flow, echogenic signals within the vessel lumen, and visualization of filling defects by color Doppler studies. Systematic reviews have demonstrated

Table 127.2 Risk Categories of Venous Thromboembolism in Surgical Patients without Prophylaxis

Risk Category	Calf DVT	Proximal DVT	Fatal PE
High	40%-80%	10%-30%	1%-5%
Major orthopedic surgery of the lower limb			
Major general surgery in patients >40 years with cancer or recent DVT or PE			
Multiple trauma			
Thrombophilia			
Moderate	10%-40%	2%-10%	0.1%-0.8%
General surgery in patients >40 years that lasts 30 minutes or more without additional risk factors			
General surgery in patients <40 years receiving estrogen or with a history of DVT or PE			
Emergency cesarean section in women >35 years			
Low	<10%	<1%	<0.01%
Minor surgery (i.e., <30 minutes in patients >40 years without additional risk factors)			
Uncomplicated surgery in patients <40 years without additional risk factors			

DVT, deep venous thrombosis; PE, pulmonary embolism.

Table 127.3 Wells Prediction Rules: Clinical Evaluation Table for Predicting Pretest Probability of Deep Venous Thrombosis

Clinical Characteristic	Score
Active cancer (treatment ongoing, within previous 6 months, or palliative)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden >3 days or major surgery within 12 weeks requiring general or regional anesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling 3 cm larger than asymptomatic side (measured 10 cm below tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (nonvaricose)	1
Alternative diagnosis at least as likely as deep venous thrombosis	-2

Clinical probability: low, ≤ 0 ; intermediate, 1-2; high, ≥ 3 . In patients with symptoms in both legs, the more symptomatic side is used.
 From Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. *Lancet* 1997;350:1795-1798.

FIGURE 127.1 Acute deep venous thrombosis of popliteal vein. Note the intraluminal filling defect (arrowheads) and “tram-tracking” of contrast material around the thrombus. (From Sokolof J, Knight R. *Deep venous thrombosis*. In Frontera WR, Silver JK, Rizzo TD Jr, eds. *Essentials of Physical Medicine and Rehabilitation*, 2nd ed. Philadelphia, WB Saunders, 2008.)

high sensitivities and specificities for the diagnosis of DVT in the proximal lower extremity by ultrasonography. However, sensitivities are poor for determination of the presence of calf vein thrombosis. Visualization of calf veins by ultrasonography is technically more difficult and less reliable than diagnosis of venous thrombus in the area between

FIGURE 127.2 Chronic lower extremity deep venous thrombosis with abundant collaterals. (From Katz DS, Math KR, Groskin SA. *Radiology Secrets*. Philadelphia, Hanley & Belfus, 1998.)

the trifurcation of the popliteal vein and the femoral vein in the groin.

Impedance plethysmography, a noninvasive diagnostic test for detection of blood vessel occlusion, determines volumetric changes in the limb by measuring changes in its girth as indicated by changes in the electric impedance of mercury-containing polymeric silicone tubes in a pressure cuff. The method is based on the principle that any circumferential rate of change in a limb segment is directly proportional to the volumetric rate of change, which in turn reflects occlusion of venous and arterial blood flow. However, the technique does not accurately identify the presence or absence of partially obstructing thrombi in major vessels [13]. Impedance plethysmography has limitations including the possibility of false-positive results because of arterial insufficiency and muscle tension [14].

D-dimer assay has emerged as a method to help predict the presence of DVT. D-dimer is a degradation product of the cross-linked fibrin blood clot and is typically elevated in patients with DVT. However, D-dimer levels may also be elevated in a variety of nonthrombotic disorders, including recent major surgery, hemorrhage, trauma, malignant disease, and sepsis. Because of the high sensitivity and low specificity of the D-dimer assay, it is a good tool for exclusion of DVT if the test result is negative. However, a high level does not have as much clinical value.

The first step in the diagnostic approach is the determination of risk. Patients can be separated by clinical criteria into high-, moderate-, and low-risk categories. All symptomatic patients thought to have DVT should, at the very least, undergo venous ultrasound imaging of the proximal venous system. Patients at moderate or high risk should have the ultrasound study repeated in 1 week. DVT also may be ruled out on the basis of a negative result of the D-dimer assay. If the D-dimer assay result is positive, a follow-up ultrasound study in 1 week is indicated.

Magnetic resonance venography is as accurate as contrast venography for the diagnosis of DVT. This was illustrated in a study that evaluated 85 patients thought to have DVT, all of whom underwent both magnetic resonance and contrast venography [15]. Although the diagnostic accuracy of magnetic resonance venography is comparable to that of contrast venography, outcome data are lacking. In addition, the present high cost of magnetic resonance venography makes it unlikely that it will gain prominence as a noninvasive test for DVT. However, magnetic resonance venography is a useful approach when contrast venography is required but precluded because of allergy to contrast media.

Differential Diagnosis

Claudication
Ruptured popliteal (Baker) cysts
Cellulitis
Hematoma
Lymphedema
Superficial thrombophlebitis
Drug-induced edema
Calf muscle pull or tear

Treatment

Initial

The most appropriate choice of prophylaxis depends on the clinical scenario and the risk-benefit profile for a particular patient. The prophylactic options that are currently available for hospitalized medical patients include low-dose unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), fondaparinux, aspirin, warfarin, intermittent pneumatic compression, and graduated compression stockings [16]. UFH and LMWH have been shown to reduce venous thromboembolic risk in hospitalized medical patients, but neither agent altered mortality [17]. On direct comparison, LMWH was more effective than UFH in preventing DVT [17]. Large meta-analyses comparing LMWH with UFH in general and orthopedic surgery have shown that LMWH is safer and more efficacious than UFH [18].

Fondaparinux has been approved by the Food and Drug Administration for the prophylaxis of DVT in patients undergoing surgery for hip fracture, hip replacement, or knee replacement; for extended DVT prophylaxis after hip fracture surgery; and for patients at risk for thromboembolic complications after abdominal surgery [19]. The approved dose for prevention of postoperative DVT is 2.5 mg subcutaneously once daily (in adults over 50 kg; prophylaxis is contraindicated in patients <50 kg), to be initiated 6 to 8 hours after completion of surgery.

Antiplatelet agents such as aspirin reduce the risk of DVT and pulmonary embolism in some patients; however, there is little evidence that antiplatelet agents have a significant effect on the prevention of venous thromboembolic events in medical patients. Also, low-dose aspirin did not significantly reduce the rate of recurrence of venous thromboembolism but resulted in a significant reduction in the rate of major vascular events, with improved net clinical benefit [19]. The 2012 American College of Chest Physicians guidelines

did not recommend the use of aspirin, either alone or in combination, as prophylaxis against DVT in any medical patient group [20].

Low-dose warfarin is better than aspirin or placebo in patients with hip fractures but may not be satisfactory in preventing DVT after elective hip and knee surgery. The use of warfarin can be associated with a transient hypercoagulable state in the first 36 hours after administration because it causes a rapid decline in protein C levels before the anticoagulant effect, which does not occur until 36 to 72 hours after drug administration.

Mechanical DVT prophylaxis can be achieved with intermittent pneumatic leg compression, intermittent pneumatic foot compression, or graduated compression stockings. Intermittent pneumatic leg compression provides increases in peak velocity and flow in the common femoral vein and is better than placebo in preventing DVT. Intermittent pneumatic foot compression is a high-pressure system that exerts compression limited to the foot. These devices are best for patients who undergo lower extremity orthopedic surgery and cannot be fitted with the intermittent pneumatic leg compression devices. The intermittent pneumatic foot compression offers no advantage over LMWH in the prevention of DVTs, except for a lower rate of bleeding complications. Graded compression elastic stockings work by increasing venous blood flow velocity. Knee-length stockings are sized to fit, and they deliver graduated pressure of 40 mm Hg at the ankle, 36 mm Hg at the lower calf, and 21 mm Hg at the upper calf. Recent clinical practice guidelines from the American College of Chest Physicians recommend the use of either intermittent pneumatic compression or graduated compression stockings over no mechanical prophylaxis in acutely ill hospitalized medical patients at increased risk for thrombosis who are bleeding or are at high risk for major bleeding [20].

The optimal duration of pharmacologic prophylaxis varies with individual risk and clinical situation. Current standard of care is to stop prophylaxis 7 to 10 days after a surgical procedure or when medical patients are ambulating freely. After major orthopedic surgery, prolonged prophylaxis of 4 to 6 weeks is most advantageous. In patients with spinal cord injuries, prophylaxis is best maintained for 6 to 10 weeks.

In someone who presents with a DVT, the primary goal of treatment is to prevent extension of the clot, recurrence of the thrombosis, acute pulmonary embolism, and development of late complications of DVT (e.g., post-thrombotic syndrome, chronic thromboembolic pulmonary hypertension, and chronic venous insufficiency). The cornerstone of medical treatment of DVT is anticoagulation therapy. Anticoagulation therapy is indicated in patients with symptomatic proximal lower extremity DVT because pulmonary embolism may occur in up to 50% of untreated individuals [21]. One study showed death in 26% of patients who had clinically suspected pulmonary embolism and did not receive anticoagulation, compared with no deaths in the treatment group [22]. Current recommendations per the 2012 American College of Chest Physicians evidence-based clinical practice guidelines for antithrombotic and thrombolytic therapy are that patients with DVT or pulmonary embolism should be treated acutely with LMWH, fondaparinux, intravenous UFH, or dose-adjusted subcutaneous UFH [20]. An analysis of 16 systematic reviews of clinical trials revealed that there is high-quality evidence to support the use of

LMWH over UFH in the treatment of established DVT [23]. Furthermore, the risk of major bleeding during initial therapy appears to be reduced with these agents compared with UFH [23]. When UFH is used, the dose should be sufficient to prolong the activated partial thromboplastin time to 1.5 to 2.5 times the mean of the control value, or the upper limit of the normal activated partial thromboplastin time range [24].

Many medical centers have adopted weight-adjusted nomograms to increase the likelihood of obtaining a therapeutic anticoagulation effect early. The nomogram that has been found to achieve the most rapid acquisition of the target activated prothrombin time is an initial bolus of 80 units/kg of UFH followed by an infusion rate of 18 units/kg per hour. Activated prothrombin time should be checked every 4 to 6 hours until a therapeutic range of 1.5 is achieved. The duration of UFH treatment ranges between 4 and 10 days. Patients with a large iliofemoral vein thrombosis or major pulmonary embolism require a 7- to 10-day course of heparin, with a delay in the initiation of warfarin until the activated prothrombin time is in the therapeutic range. Studies demonstrate that a 4- to 5-day course of heparin with warfarin administered within 24 hours of heparin initiation in patients without major pulmonary embolism of large proximal clots was as effective as 9 to 10 days of UFH alone.

LMWHs are fragments of UFH produced by either chemical or enzymatic depolymerization. LMWHs display improved bioavailability, dose-independent clearance, and more predictable dose response compared with UFH. Therefore, these agents can usually be given once or twice daily subcutaneously in weight-adjusted doses without laboratory monitoring. The U.S. Food and Drug Administration has approved two LMWHs, dalteparin (Fragmin) and enoxaparin (Lovenox), for perioperative DVT prophylaxis (Table 127.4). There are two other LMWHs available for use in DVT treatment: tinzaparin (Innohep) and nadroparin.

Enoxaparin and tinzaparin are approved for DVT treatment in the United States and Canada. Dalteparin and nadroparin are approved for this use only in Canada. Ardeparin (Normiflo) is another LMWH previously used for DVT treatment, but it was later withdrawn from the market. Enoxaparin can be used for hospitalized patients with DVT with or without pulmonary embolism and for outpatient treatment of DVT without pulmonary embolism.

Unmonitored outpatient therapy with LMWH is thought to be as safe and effective as in-hospital intravenous administration of UFH in patients with proximal DVT [25]. Like patients receiving UFH, those treated with LMWH should begin taking warfarin within 24 to 48 hours. LMWH can be discontinued after a minimum of 5 days, provided the international normalized ratio (INR) has been therapeutic for 2 consecutive days.

Thrombolytic therapy has a limited role in the treatment of DVT. It has been suggested that pharmacologic lysis of DVT could prevent post-thrombotic syndrome if complete lysis can be achieved before valve destruction occurs. However, thrombolysis, whether it is given systemically or by catheter, is expensive, the risk of bleeding complications is high, and the evidence of additional benefit is not convincing. Thrombolysis should be reserved for patients with massive iliofemoral thrombosis or unstable cardiac or pulmonary disease with no contraindications to thrombolytic therapy.

After initial treatment with LMWH, long-term anticoagulation therapy to prevent recurrent DVT is needed.

Oral anticoagulation with warfarin should prolong the INR to a target of 2.5 (range, 2-3), which generally is considered effective in preventing recurrent DVT, and risk of bleeding is lower than with higher INR levels. If oral anticoagulants are contraindicated or inconvenient, long-term therapy can be undertaken with adjusted-dose UFH, LMWH, or fondaparinux. Because of ease of use, especially in the outpatient setting, LMWH or fondaparinux is preferred to UFH [26].

Treatment duration ranges between 3 and 6 months; the short duration is reserved for those who had some risk factor (e.g., immobility) before surgery. Indefinite therapy is preferred in patients with a first unprovoked episode of proximal DVT, who have a greater relative risk of recurrent venous thromboembolism and a relatively lower concern about the burdens of long-term anticoagulant therapy [26].

The risk of recurrent DVT is serious on cessation of anticoagulation treatment. There is some evidence to suggest that post-treatment residual thrombus increases the risk of recurrent DVT and mortality [27]. The monitoring of serial D-dimer levels has been shown to be useful in determining the likelihood of DVT recurrence [28]. Treatment is indicated for at least 12 months in patients with recurrent DVT or for individuals with continuous risk factors for thromboembolic disease, such as malignant disease [25]. Untreated calf vein thrombosis does not commonly result in clinically significant pulmonary embolism unless the thrombus extends into the proximal venous segments, which occurs in about 25% of the cases. It is safe to monitor calf thrombi with serial venous ultrasound examinations or impedance plethysmography and to initiate therapy only if the thrombus extends into the popliteal or more proximal veins. Treatment of superficial venous thrombosis is usually not indicated. Pregnant women with DVT are classically treated

Table 127.4 U.S. Food and Drug Administration–Approved Uses of Low-Molecular-Weight Heparins

Name	FDA-Approved Indications	Dosage
Dalteparin (Fragmin)	DVT prophylaxis after hip replacement	5000 units SC daily; start 2500 units SC \times 1 dose 4-8h postop; allow >6h between first and second doses
Enoxaparin (Lovenox)	DVT prophylaxis after knee surgery	30mg SC q12h
	DVT prophylaxis after hip surgery	30mg SC q12h or 40mg SC daily
	DVT prophylaxis after abdominal surgery	40mg SC daily
	Inpatient treatment of acute DVT with or without PE	1 mg/kg SC q12h or 1.5 mg/kg SC daily
	Outpatient treatment of acute DVT without PE	1 mg/kg SC q12h

DVT, deep venous thrombosis; PE, pulmonary embolism; SC, subcutaneously. From Sokolof J, Knight R. Deep venous thrombosis. In Frontera WR, Silver JK, Rizzo TD Jr, eds. *Essentials of Physical Medicine and Rehabilitation*, 2nd ed. Philadelphia, WB Saunders, 2008.

with subcutaneous UFH or LMWH at full doses until delivery. Current recommendations indicate that the patient should be switched to UFH 2 weeks before the expected delivery, and a 4- to 6-week course of warfarin should be completed after delivery. Warfarin freely crosses the placental barrier, and therefore it is contraindicated during pregnancy but is safe for the mother and nursing child after delivery.

Rehabilitation

There is no strict contraindication to therapeutic exercises and ambulatory activities after DVT, but it is recommended that these activities be suspended until the patient is in the therapeutic range for heparin or has been receiving LMWH for 24 hours. On the other hand, physical and occupational therapy ordered immediately after high-risk surgical procedures can greatly improve a patient's postoperative mobility and lessen the chance for development of DVT.

Procedures

Inferior vena caval filters are indicated in patients with DVT who have an absolute contraindication to anticoagulation, high risk of bleeding, or recurrent DVT despite adequate anticoagulation. Caval interruption has been found to be effective in preventing subsequent pulmonary embolism; however, this is counterbalanced by the increased incidence of recurrent DVT. Patients who have significant but temporary contraindications to the use of anticoagulants who receive caval interruption devices should begin taking anticoagulation medication as soon as possible after placement.

Surgery

Surgical removal of acute DVT by thrombectomy or embolectomy is rarely used. It should be considered only in patients with massive thrombosis and compromised arterial circulation who do not respond to or who have an absolute contraindication to thrombolytic therapy.

Potential Disease Complications

If untreated, proximal DVT is linked with a 10% immediate risk of fatal pulmonary embolism and approximately 20% higher risk for development of a severe post-thrombotic syndrome 5 to 10 years later [29] (Fig. 127.3). There are two predominant patterns of DVT: an ascending pattern, with DVT arising in the calf veins; and a descending pattern, with DVT occurring initially in the iliac or common femoral vein. The descending pattern more commonly results in pulmonary embolism. Post-thrombotic syndrome is a condition characterized by chronic edema and debilitating pain and can lead to ulceration, infection, or, in rare cases, amputation. Heparin use and the wearing of graduated compression stockings have been associated with a lower risk for development of post-thrombotic syndrome.

Potential Treatment Complications

All pharmacologic anticoagulation agents alter the hemostatic mechanisms to some extent by decreasing blood coagulation

FIGURE 127.3 Frontal image from subsequent perfusion lung scan shows a corresponding peripheral, pleura-based area of absent perfusion in the right midlung (arrowheads). The ventilation study showed diminished ventilation in this area, consistent with pulmonary embolus with infarction, and multiple unmatched perfusion defects were seen in the left lung, indicating that the probability of pulmonary embolism is high. (From Katz DS, Math KR, Groskin SA. *Radiology Secrets*. Philadelphia, Hanley & Belfus, 1998.)

or platelet function, and all carry a risk of bleeding. Both UFH and LMWH are associated with similar increased risk of bleeding complications. Heparin-induced thrombocytopenia is a potential complication of heparin use and can be seen slightly less commonly with LMWH compared with UFH because of the lower affinity of LMWH for platelet binding. A diagnosis of heparin-induced thrombocytopenia is made when there is a 50% reduction in platelet count or a presence of antiplatelet antibodies. Once the diagnosis is made, all heparin products are contraindicated. Skin necrosis is a rare complication of warfarin use, and it can be prevented if high-dose warfarin is delayed until the activated prothrombin time is therapeutic with heparin. Complications from caval interruption include problems related to the deployment of the device: hemorrhage, hematoma, femoral artery injury, femoral nerve injury, infection, and site pain. Another potential complication is pulmonary embolism from embolization of the device itself or from failure of the device to capture an embolus. A clot-laden caval interruption device can impede venous flow and lead to lower extremity venous stasis and edema. Osteoporosis and risk of bone fracture are associated with long-term use of UFH [30], but the risk may be less with LMWH [31]. Contraindications to the use of warfarin include advanced liver disease, alcoholism, poor compliance with follow-up, poorly controlled hypertension, major bleeding, and pregnancy [32].

CHAPTER 128

Diabetic Foot and Peripheral Arterial Disease

Timothy R. Dillingham, MD, MS
Diane W. Braza, MD

Synonyms

Vascular claudication
Poor circulation
Arterial insufficiency

ICD-9 Codes

250.00 Diabetes mellitus
250.60 Diabetic neuropathy
443.9 Peripheral arterial disease

ICD-10 Codes

E11.9 Type 2 diabetes without complications
E11.40 Type 2 diabetes with diabetic neuropathy, unspecified
I73.9 Peripheral vascular disease, unspecified

Definition

The incidence of lower limb amputations due to vascular disease has increased in the United States by approximately 20% during the last decade, disproportionately in minorities [1]. Persons with diabetes mellitus and peripheral vascular disease should be identified and prophylactic foot education and preventive care instituted to reduce the risk of limb loss [2].

Diabetes mellitus, a multisystem disease, causes two conditions that place the foot at high risk for amputation: polyneuropathy and peripheral arterial disease (PAD). Diabetes affects about 25.8 million Americans [3]. Diabetes is also on the rise in the United States, particularly in African American and Hispanic populations [4]. Data from the Framingham Heart Study [5] revealed that 20% of

symptomatic patients with PAD had diabetes, but the true prevalence of PAD in patients with diabetes has been difficult to determine as most patients are asymptomatic, many do not report their symptoms, screening modalities have not uniformly been agreed on, and pain perception may be blunted by the presence of peripheral neuropathy [6].

Risk factors for diabetic ulcers include male sex, hyperglycemia, and diabetes duration. Foot ulcers often result from severe macrovascular disease, and diabetic neuropathy exacerbates the risk [7]. More than 60% of nontraumatic lower limb amputations occur in people with diabetes, underscoring the need to prevent foot ulcers and subsequent limb loss [8]. Multidisciplinary clinics that identify and manage patients with at-risk feet have demonstrated impressive reductions of 44% to 85% in the incidence of foot ulcers and lower limb amputations [9]. Minor foot trauma in a person with poor underlying circulation and reduced sensation can lead to skin ulceration. Skin ulcers, if they fail to heal, may lead to gangrene and progress to a point such that an amputation becomes necessary. This sequence of events can often be prevented before it starts.

Numerous studies have further shown that attention to lifestyle modification can dramatically reduce progression to type 2 diabetes [10]. The importance of identifying and treating a core set of risk factors (prediabetes, hypertension, smoking, dyslipidemia, and obesity) cannot be overstated [11].

Atherosclerosis is a vascular disease that can involve the peripheral arterial system. PAD is underdiagnosed, undertreated, and increasing in prevalence [12]. The American Heart Association estimates that 8 to 12 million Americans have PAD and that nearly 75% of them are asymptomatic. Annually, approximately 1 million Americans develop symptomatic PAD [13]. Despite its association with other cardiovascular risks including stroke and heart disease, only 25% of Americans with PAD are undergoing active treatment [14]. Major risk factors associated with the development of PAD or that accelerate its progression are high plasma cholesterol and lipoprotein levels, cigarette smoking, hypertension, diabetes, hyperhomocysteinemia, older age, positive family history, and chronic kidney disease [15–17]. African American ethnicity is a strong and independent risk

factor for PAD [8]. Hypertension is an important risk factor for PAD, conferring a twofold to threefold increased risk for development of PAD [18]. The risk of PAD is increased two to four times by diabetes [19]. Given that men have more risk factors for PAD, they are more commonly affected than women are.

Symptoms

The patient with a diabetic foot may demonstrate no symptoms because peripheral neuropathy can result in a lack of sensation. Peripheral neuropathy can mask painful ulcers and ischemic skin. Foot collapse due to Charcot joints can progress asymptotically. Alternatively, diabetic patients can have pain sensations in the feet from sensory polyneuropathy, including burning, tingling, and painful numbness. Because of impaired sensation, patients may report imbalance and falls.

Persons with PAD have claudication pain with walking because of insufficient arterial blood supply to meet the demand of exercising muscles. Pain with vascular claudication is typically in the calf, worsened with ambulation and relieved by resting [20]. Symptoms of pain, ache, or cramp with walking can also occur in the buttock, hip, thigh, or calf [20]. Patients with neurogenic claudication due to spinal stenosis can have similar leg or calf pain with walking but must bend at the waist or sit to relieve the symptoms. Persons may present with gangrene, ischemic ulcers on the distal foot, or, when PAD is severe, pain at rest.

Physical Examination

In addition to a standard physical examination, special neurovascular areas must be highlighted [21].

Inspect the skin for ulcerations, cracks, callus, or trophic changes (thin, shiny skin; distal hair loss).

Evaluate for any foot deformities that predispose it to abnormal stress distribution. These include hammer toes, collapsed foot arches due to Charcot joints, high-arch feet due to intrinsic muscle atrophy from polyneuropathy, and changes in stress distribution from previous toe or ray amputations.

Assess distal pulses, particularly dorsalis pedis and posterior tibial. If they are absent or weak, it suggests the need for further testing for vascular integrity.

Assess sensation because persons with loss of protective sensation are at risk for skin ulceration. The instrument most frequently used for detection of neuropathy is the nylon Semmes-Weinstein monofilament. Inability to perceive the 10-g force applied by a 5.07 monofilament is associated with clinically significant large-fiber neuropathy [22].

Evaluate gait and balance. Peripheral neuropathy predisposes to falls and skin trauma. Probe any ulcers with sterile cotton-tipped applicators or surgical instruments. If bone is reached, this identifies persons with osteomyelitis, and other special bone imaging is unnecessary [23]. Assess shoes for uneven wear patterns, areas of breakdown, and width of the toe box.

Assess skin for redness and pressure points.

Functional Limitations

Persons with diabetes can develop peripheral polyneuropathy with loss of position sense and weakness. These can lead to gait instability and falls. Persons with PAD are often

limited in community ambulation and vocational activities because of pain from claudication.

Diagnostic Studies

There are many noninvasive and invasive tests for PAD that are beyond the scope of this discussion. Angiography can identify surgically remediable lesions.

In the outpatient setting, the ankle-brachial index, a ratio of Doppler-recorded systolic pressures in the lower and upper extremities, is a convenient, accurate, noninvasive test that provides objective assessment of lower limb vascular status for screening and diagnosis of PAD [24]. Based on the results of the Ankle Brachial Index Collaboration, values above 1.40 indicate noncompressible arteries. Normal values are 1.00 to 1.40; borderline, 0.91 to 0.99; and abnormal, 0.90 or less [25]. The American College of Cardiology Foundation and American Heart Association Task Force on Practice Guidelines recommend resting ankle-brachial index to establish the diagnosis of lower extremity PAD in patients with exertional leg symptoms, nonhealing wounds, and age 65 years and older or 50 years and older with a history of smoking or diabetes [25]. Measurement of systolic pressure in the foot also provides a measure of arterial integrity.

Transcutaneous oximetry is the best method for assessment of cutaneous ischemia [9]. Transcutaneous oximetry pressures of more than 40 mm Hg are normal; pressures of 20 to 40 mm Hg indicate moderate disease, and potential for healing of a skin ulcer is less likely. With pressures below 20 mm Hg, severe skin ischemia is present, and skin healing is poor.

Systolic blood pressures in the foot are also helpful in quantifying the severity of ischemia. Persons with ischemic ulcers and ankle systolic pressures of less than 40 to 60 mm Hg are considered to have severe ischemia. Persons with persistently recurring ischemic rest pain and ankle systolic pressures of 50 mm Hg or less are severely involved [9].

If a person complains of numbness in the legs or feet or has low back pain, electrodiagnostic testing should be conducted to identify whether peripheral polyneuropathy is present or whether lumbosacral radiculopathy is responsible for these symptoms. Nerve conduction study findings may include reduced sensory and motor amplitude, latencies, and slowed conduction velocity. Electromyographic findings in radiculopathy include increased insertional activity, abnormal spontaneous activity, and changes in motor unit morphology; when these electromyographic findings are seen in a myotomal pattern, this suggests radiculopathy.

Differential Diagnosis [15]

NONVASCULAR

Neurogenic claudication from lumbar spinal stenosis
Calf pain due to S1 radiculopathy
Foot pain due to plantar fasciitis
Pain in legs and feet due to polyneuropathy
Arthritis of the hips
Restless legs syndrome

VASCULAR

Arterial embolus
Deep venous thrombosis
Thromboangiitis obliterans (Buerger disease)

Treatment

Initial

Efforts to achieve smoking cessation are recommended for individuals with lower extremity PAD. Cigarette smoking is the most important risk factor for development of PAD [26]. Observational studies have demonstrated that the risk of death, myocardial infarction, and amputation is substantially greater in those individuals with PAD who continue to smoke [25]. The risk of smoking for vascular disease is even greater for women than for men [27].

For diabetes control, minimize hyperglycemia. The presence of PAD is 20% to 30% higher in diabetics than in the general population. According to recently published guidelines, patients with diabetes and PAD should have aggressive control of blood glucose levels with a hemoglobin A_{1c} level below 7.0% or as close to 6% as possible to reduce the risk of microvascular complications [25].

For hypertension control, management of blood pressure is required. The desired blood pressure range is less than 140/90 mm Hg or less than 130/80 mm Hg if diabetes or renal insufficiency is present [12]. Choice of antihypertensive medication is generally guided by the presence of underlying diseases, such as diabetes, chronic kidney disease, or proteinuria [12].

Elevated total and low-density lipoprotein cholesterol levels, reduced high-density lipoprotein level, and hypertriglyceridemia are associated with lower extremity PAD [20]. Several clinical trials have demonstrated the benefits of lipid-lowering therapy in patients with PAD and coexistent coronary and cerebral arterial disease [15].

High serum homocysteine levels are associated with a twofold to threefold increased risk for PAD [28]. Dietary supplementation with B vitamins and folate may lower homocysteine levels, but no controlled trials to date demonstrate this clinical benefit in PAD [15].

Aerobic exercise can improve lipid profiles and optimize weight, blood pressure, and glycemic control, thus playing a role in medical management of PAD.

The 2012 American College of Chest Physicians Evidence-Based Clinical Practice Guidelines for antithrombotic therapy and prevention of thrombosis recommend aspirin, 75 to 100 mg/day, for individuals with asymptomatic PAD for the primary prevention of cardiovascular events. For secondary prevention of cardiovascular disease in patients with symptomatic PAD, long-term aspirin, 75 to 100 mg/day, or clopidogrel, 75 mg/day, is recommended [29]. Warfarin is not recommended. For patients with refractory claudication despite exercise therapy and smoking cessation, cilostazol, 100 mg twice daily, is recommended in addition to aspirin, 75 to 100 mg/day, or clopidogrel, 75 mg/day [29] (Table 128.1).

Rehabilitation

Exercise

Patients with symptomatic PAD have impaired walking tolerance. A program of supervised exercise is recommended for patients with intermittent claudication. A meta-analysis of training programs concluded that supervised exercise

Table 128.1 Medical Management of Peripheral Arterial Disease

Smoking cessation
Lipid modification: target low-density lipoprotein cholesterol level <100 mg/dL
Treatment of hypertension: target blood pressure <140/90 mm Hg
Control of hyperglycemia: target hemoglobin A _{1c} level <7%
Antiplatelet therapy: aspirin, 75-100 mg daily, or clopidogrel, 75 mg daily
Aerobic exercise

therapy showed statistically significant and clinically relevant differences in improvement of maximal treadmill walking distance compared with nonsupervised exercise therapy regimens of approximately 150 meters [30]. A study comparing the efficacy of cycle training versus treadmill exercise in the treatment of intermittent claudication concluded that cycle exercise is not effective in improving walking performance in all claudication patients [31]. A cross-transfer effect between training modes was noted for patients reporting common limiting symptoms at baseline for both cycling and walking. Therefore, the current recommendation for exercise in intermittent claudication is walking [31]. Exercise should be performed for a minimum of 30 to 45 minutes, at least three times per week. Supervised exercise can induce increases in maximal walking ability that exceed those attained with drug therapies alone and translate into improved functional ability [26,32]. Exercise is contraindicated in the presence of an ischemic ulcer or rest pain.

Foot Care

Meticulous attention to the feet by both patient and physician and detailed education of the patient are the mainstays of preventive foot care. Deformities should prompt the clinician to consider custom shoe inserts to distribute pressures evenly over the foot. Extra-depth shoes may be necessary to accommodate hammer toes. Extra-width shoes can accommodate bunions and other foot deformities. Sneakers may be another alternative for persons with or without mild foot deformities. However, if there are any aberrations in foot bone architecture, custom footwear with molded sole inserts is desirable. Gentle rocker-bottom modifications affect weight transfer from heel to toe during the gait cycle.

Skin Ulcers

Early treatment of skin infections with antibiotics is warranted along with minimization or elimination of weight bearing during healing. Achievement of a therapeutic antibiotic concentration at the site of infection is key. Intravenous antibiotics may therefore be necessary for patients with severe infection or systemic illness and for treatment of pathogens that are not susceptible to oral agents [33].

For more involved wounds, débridement with dressing changes or whirlpool is sometimes necessary. Deep infections into bone or infections that extend along fascial planes require débridement. If osteomyelitis is suspected, at least a 6-week course of parenteral or oral antibiotic therapy guided by culture samples obtained during débridement is an effective clinical approach. Other wound care measures,

such as total contact casting, can assist with improved healing of plantar surface ulcers [34]. However, when both PAD and infection are present or the patient has a heel ulcer, outcome is poor and alternative strategies should be sought [34].

Hyperbaric oxygen therapy may improve wound healing and reduce the rate of amputation [35]. However, given its expense and limited resource, it is mostly limited to deep infections unresponsive to standard therapy.

Edema hinders wound healing. Measures to control edema, such as leg elevation, compression stockings, and pneumatic compression devices, are often used [36].

Procedures

An acute painful, pale, pulseless limb should be evaluated emergently as this indicates acute arterial compromise. Likewise, gangrene or an ulcer extending to bone should prompt surgical consultation. Sharp débridement for a necrotic wound is often necessary to remove devitalized tissue and to promote healing of ulcers.

Percutaneous endovascular interventions to treat peripheral arterial occlusion include transluminal angioplasty with balloon dilation, stents, atherectomy, laser, cutting balloons, thermal angioplasty, and fibrinolysis or fibrinectomy. This intervention may be necessary to provide enough oxygenated arterial blood to a limb to heal open sores, to improve symptoms of claudication, or to save an extremity at risk for amputation [22].

Endovascular procedures are indicated for individuals with severe vocational or lifestyle-limiting disability due to intermittent claudication for whom exercise and pharmacologic therapy have failed. Clinical features must suggest a reasonable likelihood of symptomatic improvement with endovascular intervention with a favorable risk-benefit ratio [25].

Outcomes of percutaneous transluminal angioplasty and stents depend on anatomic and clinical factors. Durability of patency after percutaneous transluminal angioplasty is greatest for lesions in the common iliac artery and decreases distally. Durability decreases with increasing length of the stenosis, multiple and diffuse lesions, poor-quality runoff, diabetes, renal failure, and smoking. Hormone replacement in women has been shown to decrease patency of iliac stents [25].

Surgery

Surgical treatment of intermittent claudication is indicated in individuals who do not derive adequate functional benefit from nonsurgical therapies, who have limb arterial anatomy favorable to a durable clinical result, and in whom the risk of cardiovascular complications is low.

The exact surgical procedure (aortobifemoral bypass, aortoiliac bypass, iliofemoral bypass, axilofemoral-femoral bypass) is determined by the site and severity of the occlusive lesion, prior revascularization attempts, general medical condition, and desired outcome [25].

Similar considerations are given in the management of limb-threatening ischemia. Surgical lower limb amputation may be necessary if revascularization attempts are unsuccessful in the management of limb-threatening ischemia or gangrene.

Potential Disease Complications

As a result of PAD, patients may develop ischemic pain from arterial insufficiency defined as claudication (pain with ambulation) or rest pain. Other potential complications include nonhealing or slow to heal foot ulcers, cellulitis, and deeper wound infections in the foot. If those complications cannot be treated medically, amputation of a portion of the lower limb may be necessary to save the remaining viable limb and to prevent disseminated infection. Charcot joints and bone fractures in the foot due to diabetic polyneuropathy can be seen, potentially leading to skin ulcer and breakdown.

Potential Treatment Complications

Potential treatment complications depend on the intervention implemented. For example, in surgical revascularization, infection of arterial bypass grafts, ischemic cardiac disease, and worsening of renal azotemia are potential complications. Patients undergoing wound débridement should be closely observed for possible infection of foot ulcers after débridement. For PAD patients initiating an exercise program, potential complications include cardiac ischemic events, given the strong correlation of arterial disease and cardiovascular disease. Therefore, in such patients, supervised exercise instruction after cardiac stress testing is initially recommended to stratify patients at potential risk.

ICD-9 Codes

438.82 Other late effects of cerebrovascular disease, dysphagia
787.2 Dysphagia, difficulty in swallowing

ICD-10 Codes

I69.891 Dysphagia following other cerebrovascular disease
R13.10 Dysphagia, difficulty in swallowing

Definition

Dysphagia generally refers to any difficulty with swallowing, including occult or asymptomatic impairments. It is a common problem, affecting one third to one half of all stroke patients [1] and about one sixth of elderly individuals [2]. It is frequent in head and neck cancer, traumatic brain injury, degenerative disorders of the nervous system, gastroesophageal reflux disease, and inflammatory muscle disease (Table 129.1). Dysphagia is classified according to the location of the problem as oropharyngeal (localized to the oral cavity or pharynx, not just the oropharynx) or esophageal. It may also be classified as mechanical (due to a structural lesion of the foodway) or functional (caused by a physiologic abnormality of foodway function) [3].

Sudden onset is suggestive of stroke. Concomitant limb weakness suggests a neurologic or neuromuscular disorder. Medication-induced dysphagia is commonly overlooked. Medications that impair level of consciousness (such as sedatives and tranquilizers), have anticholinergic effects (tricyclics, propantheline), or can damage mucous membranes

(nonsteroidal anti-inflammatory drugs, aspirin, quinidine) may also cause dysphagia [4].

Symptoms

The most common symptoms of dysphagia are coughing or choking during eating [5] and the sensation of food sticking in the throat or chest. Some of the many symptoms and signs of dysphagia are listed in Table 129.2. A history of drooling, significant weight loss, or recurrent pneumonia suggests that the dysphagia is severe. The history is most useful for identification of esophageal dysphagia; the complaint of food sticking in the chest is usually associated with an esophageal disorder. In contrast, the complaint of food sticking in the throat has little localizing value and is often caused by an esophageal disorder. Coughing and choking during swallowing suggest an oropharyngeal origin and may be precipitated by aspiration (penetration of material through the vocal folds and into the trachea). However, some patients have impaired cough reflexes, resulting in silent aspiration (without cough) [5,6]. Silent aspiration occurs in 28% to 94% of people with dysphagia, depending on the population of patients [7,8]. Patients with neurologic disorder have a higher incidence of silent aspiration. Pain on swallowing (odynophagia) may occur transiently in pharyngitis, but persistent pain is unusual and is suggestive of neoplasia. Heartburn is a nonspecific complaint that is usually not associated with swallowing but occurs after meals. Heartburn may occur in gastroesophageal reflux disease, but a more specific symptom of gastroesophageal reflux disease is regurgitation of sour or bitter-tasting material into the throat after eating.

Physical Examination

An examination of the oral cavity and neck may identify structural abnormalities, weakness, or sensory deficits. The finding of dysarthria (abnormal articulation of speech) or dysphonia (abnormal voice quality) is often associated with oropharyngeal dysphagia. However, the examination is primarily useful for finding evidence of underlying neurologic, neuromuscular, or connective tissue disease. The examination should always include trial swallows of water [9–11]. During the swallow, there should be prompt elevation of the hyoid bone and larynx. Changes in voice quality and spontaneous coughing after swallowing suggest pharyngeal dysfunction. The history and physical examination are

Table 129.1 Selected Causes of Oral and Pharyngeal Dysphagia

Neurologic Disorders and Stroke	Structural Lesions	Connective Tissue Diseases
Cerebral infarction	Thyromegaly	Polymyositis
Brainstem infarction	Cervical	Muscular

 Unexplained weight loss
 Change in dietary habits
 Recurrent pneumonia
 Dehydration

limited in their ability to detect and to characterize dysphagia, so instrumental studies are usually necessary [12].

Neurologic examination is important in the evaluation of dysphagic individuals because neurologic disorders commonly cause dysphagia. Disorders of either upper or lower motor neurons may produce dysphagia. The findings of atrophy or fasciculations of the tongue or palate suggest lower motor neuron dysfunction of the brainstem motor nuclei. In contrast to the prevailing wisdom, the gag reflex is not strongly predictive of the ability to swallow. It may be absent in normal individuals and normal in individuals with severe dysphagia and aspiration [13].

Functional Limitations

Functional limitations depend on the nature and severity of the dysphagia. Many individuals modify their diets to eliminate foods that are difficult to swallow; others require special postures or respiratory maneuvers. Some require inordinate amounts of time to consume a meal. In severe cases, tube feeding is necessary. These alterations in the ability to eat a meal can have a profound effect on psychological and social function [14]. Interaction with family and friends often centers on mealtime—family dinners,

“going out” for a drink or for dinner, “coming over” for a snack or for dessert. Difficulty in eating a meal may disrupt relationships and result in social isolation. Some patients may require supervision during meals or feel unsafe when they eat alone, causing further disruption of social and vocational function.

Diagnostic Testing

Because the mechanics of swallowing are largely invisible to the naked eye, diagnostic studies are commonly needed. The sine qua non for diagnosis of oropharyngeal swallowing disorders is the videofluorographic swallowing study (VFSS) [15]. In this test, the patient eats and drinks a variety of solids and liquids combined with barium while images are recorded with videofluorography (x-ray videotaping). The VFSS is usually performed jointly by a physician (physiatrist or radiologist) and a speech-language pathologist. A unique benefit of the VFSS is that therapeutic techniques (such as modification of food consistency, body position, or respiration) can be tested and their effects on swallowing observed during the study. A routine barium swallow study is frequently sufficient if the problem is clearly esophageal.

If a VFSS cannot be performed because of the physical limitation of the patient, the fiberoptic endoscopic evaluation of swallowing is useful to visualize the anatomy of the pharynx and larynx and vocal fold function during eating with no x-ray exposure [16]. It is also highly sensitive for detection of aspiration [8]; but it does not visualize essential aspects of swallowing, such as the oral and esophageal stages of swallowing, or critical events of pharyngeal swallowing including opening of the upper esophageal sphincter, elevation of the larynx, and contraction of the pharynx.

In cases of esophageal dysphagia, esophagoscopy is frequently necessary to detect mucosal lesions or masses. Biopsy is indicated when mucosal abnormalities are detected. Manometry is useful for detection and characterization of motor disorders of the esophagus and is sometimes performed on the pharynx as well. Electromyography is indicated when neuromuscular disease is suspected and is useful for detection of lower motor neuron dysfunction of the larynx and pharynx.

Differential Diagnosis

Myocardial ischemia
 Globus sensation
 Heartburn due to gastroesophageal reflux disease
 Indirect aspiration (aspiration of refluxed gastric contents)

Treatment

Initial

The treatment of dysphagia depends on its causes and mechanism. Common treatments are listed in Table 129.3. Whenever possible, initial treatment should be directed at the underlying disease process; for example, steroids for inflammatory muscle disease. Esophageal dysphagia necessitates evaluation and treatment by a gastroenterologist. When no therapy exists for the underlying disease or the

Table 129.3 Principal Treatments of Selected Disorders Affecting Swallowing

Problems	Principal Treatments
Amyotrophic lateral sclerosis	Dietary modification Compensatory maneuvers Counseling and advance directives
Carcinoma of esophagus	Esophagectomy and radiation therapy
Gastroesophageal reflux disease	Dietary modification No eating at bedtime Pharmacologic therapy Smoking cessation
Polymyositis, myasthenia gravis	Pharmacologic treatment of underlying disease (dietary modification, compensatory maneuvers, and dysphagia therapy only if necessary)
Esophageal stricture or web	Dilation
Stroke, multiple sclerosis	Dietary modification Compensatory maneuvers Dysphagia therapy

therapy is ineffective or contraindicated, rehabilitative strategies are appropriate. Patients and their family members are encouraged to learn the Heimlich maneuver; this is important because airway obstruction is potentially fatal.

Rehabilitation

Many patients benefit from a structured swallowing therapy provided by a speech-language pathologist, including instruction and supervision about diet, compensatory maneuvers, and exercise [17]. The goals of therapy are to

reduce aspiration, to improve the ability to eat and drink, and to optimize nutritional status. Therapy is individualized according to the patient's specific anatomic and structural abnormalities and the initial responses to treatment trials observed at the bedside or during the VFSS [18]. A fundamental principle of rehabilitation is that the best therapy for any activity is the specific activity itself; swallowing is generally the best therapy for swallowing disorders, so the rehabilitation evaluation is directed at identifying the circumstances for safe and effective swallowing for each individual patient.

Diet modification is a common treatment of dysphagia [19]. Patients vary in ability to swallow thin and thick liquids, and that determination is usually best made by VFSS. A patient can usually receive adequate oral hydration with either thin (e.g., water or apple juice) or nectar-thick liquids (e.g., apricot nectar, tomato juice). Rarely, a patient may be limited to honey-thick or pudding consistency if thin and thick liquids are freely aspirated. Most patients with significant dysphagia are unable to safely eat meats or similarly tough-textured foods and require a mechanical soft diet. A pureed diet is recommended for patients who exhibit oral preparatory phase difficulties, pocket food in the buccal recesses (between the teeth and the cheek), or have significant pharyngeal retention after swallowing with chewed solid foods. Maintenance of oral feeding often requires compensatory techniques to reduce aspiration or to improve pharyngeal clearance. A variety of behavioral techniques are used, including modifications of posture, head position (Fig. 129.1), and respiration, as well as specific swallow maneuvers [20].

Exercise therapy for dysphagia is indicated when the problem is related to weakness of the muscles of swallowing [21]. The choice of exercises must be individualized according

FIGURE 129.1 Turning the head toward the weak side improves pharyngeal emptying in some individuals with dysphagia due to lateral medullary infarction. This series of video prints is taken from a videofluorographic swallowing study of an individual with severe dysphagia due to lateral medullary infarction. The top images show an anteroposterior projection of swallowing with the head in anatomic position. The top left image was obtained in mid-swallow. There is stasis of barium in the left piriform recess, with only minimal flow of barium through the upper esophageal sphincter. The top right image shows the large amount of residual barium in the pharynx after swallowing. The bottom images show swallowing with the head turned toward the weak left side. The lower left image, in mid-swallow, shows enhanced flow of barium. The lower right image shows dramatically reduced retention of barium after the swallow.

FIGURE 129.2 Shaker (pronounced “shock-air”) exercise augments upper esophageal sphincter opening by strengthening the anterior suprahyoid muscles. The neck is actively flexed, raising the head so the patient can see the toes and touching the chin to the chest, without lifting the shoulders and with the mouth closed.

to the physiologic assessment. The full range of exercises is beyond the scope of this chapter, but several examples illustrate the principles.

- Tongue weakness can be treated with lingual resistance exercise [22].
- Strengthening of the anterior suprahyoid muscles is useful when the upper esophageal sphincter opens poorly. Flexing the neck against gravity while lying supine can strengthen these muscles (Fig. 129.2) [23,24].
- Vocal fold adduction exercises may be useful in cases of aspiration due to weakness of these muscles. These exercises are done several times a day whenever possible.

Procedures

VFSS functions as both a diagnostic and a therapeutic procedure for dysphagia, especially oropharyngeal dysphagia, because it can be used to test the effectiveness of modifying food consistency and other compensatory techniques [25]. Endoscopy with dilation of the esophagus is often indicated in cases of partial esophageal obstruction due to stricture or web. Dilation is also appropriate in stenosis of the upper esophageal sphincter. Endoscopy can be used for biofeedback, especially to demonstrate movements of the larynx during swallowing maneuvers. Electromyography is also used for biofeedback. Activities of the infrahyoid and suprahyoid muscles are recorded with surface electrodes during swallowing therapy. Biofeedback itself is not a dysphagia therapy but can be a useful adjunct to therapy. Surface electrical stimulation on the submental or anterior cervical muscles is a new treatment of dysphagia, but the evidence for its efficacy is weak [26].

Surgery

Surgery is rarely indicated in the care of patients with oral or pharyngeal dysphagia. The most common procedure for pharyngeal dysphagia is cricopharyngeal myotomy, during which the upper esophageal sphincter is disrupted to reduce the resistance of the pharyngeal outflow tract. However, the effectiveness of myotomy is highly controversial [27]. Esophagectomy may be necessary in case of esophageal cancer or obstructive strictures. Feeding gastrostomy (usually percutaneous endoscopic gastrostomy) is indicated when the severity of the dysphagia makes it impossible for

adequate alimentation or hydration to be obtained orally, although intravenous hydration or nasogastric tube feedings may be sufficient on a time-limited basis [28]. Orogastric tube feedings have been used successfully by patients who have absent gag reflexes and can tolerate intermittent oral catheterization. Laryngectomy or surgical closure of the larynx is rarely performed in cases of recurrent, intractable aspiration pneumonia.

Potential Disease Complications

Severe dysphagia may result in aspiration pneumonia [29], airway obstruction, bronchiectasis, dehydration, or starvation and is potentially fatal. Severe dysphagia often causes social isolation because of the inability to consume a meal in the usual manner. This can lead to clinical depression. Suicide has been reported.

Potential Treatment Complications

The VFSS is safe and well tolerated. Prescription of a modified diet often means the substitution of thick for thin liquids. Some patients find these unpalatable and reduce fluid intake to the point of dehydration and malnutrition. Failure to reevaluate patients in a timely manner can lead to unnecessary prolongation of dietary restrictions, increasing the risk of malnutrition and adverse psychological effects of dysphagia. Dilation of the esophagus or sphincters can result in perforation, but this complication is uncommon. Percutaneous endoscopic gastrostomy can have direct or indirect sequelae. Direct sequelae, such as pain, infection, and obstruction of the feeding tube, are common. Percutaneous endoscopic gastrostomy tube feeding can promote aspiration pneumonia in individuals with severe gastroesophageal reflux disease.

Synonyms

Myositis ossificans
Ossifying fibromyopathy
Neurogenic heterotopic ossification
Periarticular ossification
Heterotopic ossification in paraplegia
Neurogenic ossifying fibromyositis
Neurogenic osteoma
Paraosteoarthropathy

ICD-9 Codes

728.1 Muscular calcification and ossification
728.10 Calcification and ossification, unspecified
Massive calcification (paraplegic)
728.11 Progressive myositis ossificans
728.12 Traumatic myositis ossificans
Myositis ossificans (circumscripta)
728.13 Postoperative heterotopic calcification
733.99 Other and unspecified disorders of bone and cartilage
Hypertrophy of bone

ICD-10 Codes

M61.9 Calcification and ossification of muscle, unspecified
M61.20 Paralytic calcification and ossification of muscle, unspecified site
M61.10 Myositis ossificans progressiva, unspecified site
M61.00 Myositis ossificans traumatica, unspecified site

M61.40 Other calcification of muscle, unspecified site

M89.30 Hypertrophy of bone, unspecified site

Definition

Heterotopic ossification is the formation of mature, lamellar bone in nonskeletal tissue, usually in soft tissue surrounding joints [1,2]. Its exact etiology is unknown. Heterotopic ossification is commonly seen in patients with traumatic brain injury, spinal cord injury, cerebrovascular accident, burns, fractures, trauma, or muscle injuries and after total joint arthroplasty. Heterotopic ossification has also been described in medically complex patients after prolonged sedation, ventilation, critical illness, and immobilization [3,4]. In addition, heterotopic ossification has been found to be a complication after both cervical and lumbar disc replacement [5,6]. Riedel first described heterotopic ossification after trauma to the spinal cord in 1883 [7]. The term *neurogenic heterotopic ossification* has been commonly used for heterotopic ossification in patients with traumatic brain injury, spinal cord injury, and cerebrovascular accident [2,8]. The bone formation in heterotopic ossification differs from that in other disorders of calcium deposition in that heterotopic ossification results in encapsulated bone between muscle planes, which is not intra-articular or connected to periosteum [9].

The incidence rate reported in the literature varies from 11% to 75% in patients with severe traumatic brain injury and spinal cord injury [10,11]. Approximately 33% of patients with traumatic brain injury and spinal cord injury diagnosed with heterotopic ossification show a loss of joint range of motion; 10% to 16% progress to complete joint ankylosis [2,10]. The incidence of heterotopic bone formation after total hip arthroplasty and acetabular fracture is estimated at 16% to 53% and 18% to 90%, respectively [12].

Heterotopic ossification is both more common and more extensive in patients with severe spasticity. Increased spasticity and lower level of limb function increase the risk for development of heterotopic ossification and the rate of recurrence after surgical resection [8]. In addition, when

other factors are controlled for, the incidence of heterotopic ossification increases with body mass index in patients with acetabular fracture [13]. In patients with spinal cord injury, the number of pressure ulcers and duration of time since injury are also associated with the development of heterotopic ossification [14]. When ectopic bone is discovered in patients with paraplegia, it is never found above the level of injury. Heterotopic ossification is rarely seen in flaccid limbs [8]. Interestingly, heterotopic ossification is infrequently reported in cerebral palsy or in children with anoxic brain injury [2].

The pathogenic mechanisms of heterotopic ossification are still being investigated. Whether genetic factors or local phenomena (trauma, tissue hypoxia, venous insufficiency, edema) are triggering factors, the final common pathway is inflammation and increased blood flow in the tissues [1,8,15]. Undifferentiated mesenchymal cells in connective tissue surrounding muscle or vasculature are transformed by bone morphogenetic proteins into osteoblasts, which lay down new bone matrix [4,12,13,15–17]. The scientific literature suggests that overactive bone morphogenetic protein signaling is involved in the development of both acquired heterotopic ossification and congenital heterotopic ossification, which is seen in fibrodysplasia ossificans progressiva.

The temporal relationship between injury and initiation of ossification is not clear. However, clinical signs, symptoms, and positive diagnostic test results may appear as early as 2 weeks after injury [12]. Mineralization and true bone formation are usually completed by 6 to 18 months [8]. The extent of bone formation has been described in the Brooker classification [2,11,17–19] for heterotopic ossification of the hip (Fig. 130.1). Only class III and class IV are

Table 130.1 Brooker Classification for Heterotopic Ossification of the Hip

Class	Description
I	Islands of bone within soft tissue
II	Bone spurs from pelvis or proximal femur, at least 1 cm between bone surfaces
III	Bone spurs from pelvis or proximal femur with space between bone surfaces of less than 1 cm
IV	Apparent bone ankylosis of the hip (Fig. 130.1)

clinically significant. Although modifications to the Brooker classification have been suggested, many clinicians continue to use this system to describe the extent of heterotopic bone formation (Table 130.1).

Symptoms

Individuals demonstrate great variability in the initial symptoms and degree of heterotopic bone involvement. Patients are often asymptomatic [1,20]. In neurogenic heterotopic ossification, the most common symptom is pain (although this is often absent in spinal cord injury because of sensory deficits). Limitation to joint range of motion is commonly reported [8,12]. Symptoms range in onset from 2 weeks to 12 months after the inciting event, and patients may report warmth, swelling, and tenderness [2,11,21,22]. Heterotopic ossification may trigger autonomic dysreflexia in patients with spinal cord injury at or above the T6 level [23].

Physical Examination

Time at onset, location, and degree of heterotopic bone formation vary between individuals. Therefore, joints should be examined frequently in those at risk to assess range of motion and to assist in early diagnosis. The clinician should also inspect each joint for erythema and palpate for point tenderness or masses. The most common physical finding is decreased range of motion of the joint.

Distal joints of the hands and feet are almost never involved. Heterotopic ossification is typically limited to hips, knees, shoulders, and elbows [8]. In neurogenic heterotopic ossification secondary to traumatic brain injury or spinal cord injury, the hip is the most common joint affected [15]. Ossification is usually found inferomedial to the joint and is typically associated with adductor spasticity [2].

Functional Limitations

The loss of range of motion secondary to heterotopic ossification interferes with hygiene, transfers, and daily activities [22]. Pain from heterotopic ossification can be a significant cause of functional limitation.

Diagnostic Studies

The three-phase bone scan is the current “gold standard” for early detection of heterotopic ossification. It is possible to discover increased metabolic activity as early as 2 to 4 weeks after injury. This procedure involves intravenous injection of technetium Tc 99m-labeled polyphosphate, which is

FIGURE 130.1 Radiograph of Brooker class IV heterotopic ossification of the right hip.

FIGURE 130.2 Three-phase bone scan showing increased activity at the left hip juxta-articular ossification site.

known to accumulate in areas of active bone growth. The three phases are as follows [8,22] (Fig. 130.2):

- Phase 1: Dynamic blood flow occurs immediately after injection.
- Phase 2: Immediate static scan detects areas of blood flow after injection.
- Phase 3: Static phase involves a repeated bone scan after several hours.

A disadvantage of the three-phase bone scan is its lack of specificity. It therefore may be difficult to differentiate bone tumor, metastasis, or osteomyelitis from heterotopic ossification [8]. In addition, false-negative bone scans have been described after spinal cord injury [24].

Radiographs are readily available and economical but may not show calcification until after clinical signs and symptoms have developed or until 4 to 6 weeks after an abnormality is detected on the bone scan [11]. Heterotopic ossification has been described in three radiologic stages with variable time frames [2,25]:

1. early: increased activity on bone scan, no radiologic evidence;
2. intermediate: radiographically appearing immature bone; and
3. mature: well-developed, mature-appearing bone.

Both mature and immature bone can coexist. It is not uncommon for mature ossification to radiographically obscure immature bone [2]. Therefore, radiographic determination of the maturity of heterotopic bone is often unreliable [2,8].

Computed tomographic scanning is rarely used in detection of heterotopic ossification. There has been some evidence to suggest that magnetic resonance imaging of the knee may help to confirm an early diagnosis of heterotopic ossification [26]. Both computed tomography and magnetic resonance imaging have proved especially helpful in

preoperative planning for resection to establish relationships of bone to muscle and neurovascular bundles [8,11].

Ultrasonography and angiography are not often used for the diagnosis of heterotopic ossification. However, cases have been reported in which ultrasound examination has been used to help differentiate heterotopic ossification from primary bone tumor, hematoma, or abscess. Similarly, angiography has been used to differentiate traumatic myositis ossificans from tumor and to define anatomy before surgical resection [8,12].

Many laboratory tests have been investigated for use in the diagnosis of heterotopic ossification. No one test has been found to be completely reliable with high sensitivity and specificity for heterotopic ossification. Although it is nonspecific, a widely used laboratory test for monitoring of heterotopic bone formation is the alkaline phosphatase (ALP) level. ALP has been shown to be elevated during the active bone formation of heterotopic ossification (normal range is 38 to 126 U/L). ALP levels rise as early as 2 weeks after injury, reaching a peak around 10 weeks [8]. ALP is helpful for diagnosis because it may be elevated up to 7 weeks before development of clinical symptoms [4]. Because the specificity of ALP elevation is low, it is recommended that three-phase bone scan be used to confirm suspected cases of heterotopic ossification [27].

Serum and urinary calcium concentrations, frequently nonspecific responses to trauma, do not provide any information about the ongoing ossification process and are therefore not used for diagnosis and monitoring of heterotopic ossification [15]. Other urinary markers, including hydroxyproline, deoxypyridinoline, and prostaglandin E₂, have been suggested for use in detection of heterotopic ossification [3,4,8,12]. Serum intact osteocalcin, C-reactive protein, erythrocyte sedimentation rate, and creatine kinase have been used as markers for heterotopic bone formation in

some studies. In patients with spinal cord injury, the inflammatory phase of heterotopic bone formation can be monitored by C-reactive protein levels, and creatine kinase can be used to estimate the severity of ossification [3,16]. Both C-reactive protein and creatine kinase levels may be used to assist in therapeutic and treatment decisions. When markers suggest active formation of heterotopic ossification, medical and rehabilitation treatments may be indicated; however, if markers suggest ongoing inflammation, surgical resection for definitive treatment may be delayed [16].

Differential Diagnosis

- Deep venous thrombosis
- Cellulitis or infection
- Acute arthritis
- Superficial thrombophlebitis
- Contracture
- Complex regional pain syndrome
- Spasticity
- Tumoral calcinosis
- Secondary hyperparathyroidism
- Hypervitaminosis D
- Fracture
- Gout
- Pseudogout
- Para-articular chondroma
- Calcinosis circumscripta
- Hematoma or hemorrhage

Treatment

Initial

Nonsurgical strategies for treatment of heterotopic ossification include mobilization of the joint, medications to decrease inflammation or bone formation, and prophylactic low-dose radiation therapy. These therapies and preventive strategies may be combined to improve outcome [2,20]. Spasticity and pain can be barriers to providing proper range of motion. Both should be managed appropriately to ensure that mobilization can occur.

Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used not only for analgesia of the patient but also to reduce bone formation by the inhibition of prostaglandin synthetase. NSAIDs inhibit arachidonic acid metabolism, thereby inhibiting prostaglandin production, reducing inflammation, and slowing bone metabolism.

Studies have shown that indomethacin, ibuprofen, and other NSAIDs have been effective for the prevention of heterotopic ossification in total hip arthroplasty and in high-risk spinal cord-injured patients [2,8,12,16,21,28]. A recent review suggested that NSAIDs have the greatest efficacy in preventing heterotopic ossification when they are given early after a spinal cord injury [29,30]. Indomethacin has been the most widely used NSAID in prophylaxis for heterotopic ossification and is commonly used after surgical resection to prevent recurrence. Traditionally, indomethacin is started on postoperative day 1 at a dose of 25 mg three times a day for 3 weeks and is continued for up to 2 months [2,8,17]. Shorter treatment durations have been found effective for prophylaxis [31].

Etidronate disodium (EHDP), a bisphosphonate, has been shown to delay the aggregation of apatite crystals into large, calcified clusters in patients with traumatic brain injury and spinal cord injury [2,8,10]. Although EHDP does not eradicate bone that has already formed, it reduces further progression of ossification [16]. EHDP is not routinely used for prophylaxis, but some clinicians advocate prophylactic use in high-risk spinal cord-injured patients. Bisphosphonates are thought to be most effective for treatment once the diagnosis of heterotopic ossification is established, particularly if they are given early in the disease course before there is radiographic evidence of bone formation [29,30]. The treatment recommendation for established heterotopic ossification in spinal cord injury is 20 mg/kg daily orally for 6 months [32]. For patients with traumatic brain injury, it has been suggested that oral treatment be initiated at 20 mg/kg per day for 3 months, then reduced to 10 mg/kg per day for 3 months [10].

Observational evidence suggests that warfarin is associated with a reduced incidence of heterotopic ossification in patients with spinal cord injury; however, it is not used solely for prevention of heterotopic ossification, in part because of the side effect profile [30]. After elective total hip arthroplasty, aspirin thromboprophylaxis has been shown to reduce prevalence of heterotopic ossification [33]. At the molecular level, treatments aimed at the reduction of bone morphogenetic protein signaling may help reduce formation of heterotopic bone. Although not used in clinical treatment at this time, bone morphogenetic protein receptor antagonists, retinoic acid receptor agonists, and free radical scavengers are current research targets [34].

Rehabilitation

Comprehensive physical and occupational therapy can be considered both preventive and a first-line treatment modality. Several studies have shown that early range of motion exercises are beneficial in the prevention and treatment of heterotopic ossification [9]. Some have suggested that joint manipulation may increase the inflammatory response, thereby increasing production of heterotopic bone, but there is no objective evidence to show this to be true [2]. Joint manipulation may not alter bone formation, but it can prevent soft tissue contractures and maintain functional range of motion. Because physical therapy is often difficult secondary to pain or spasticity, forceful manipulation under anesthesia has been tried but is not a standard treatment modality. Exercises to maintain joint range of motion are still considered the mainstay for prevention of heterotopic ossification [2,21]. Continuous passive motion machines are beneficial in increasing range of motion after surgical resection of heterotopic bone [4,12].

Procedures

Radiation therapy has been shown to help prevent heterotopic ossification after total hip arthroplasty and after resection of mature heterotopic bone [1,27]. It is the only therapy for heterotopic ossification that acts locally [8]. Although opinions differ as to the most effective treatment method, single doses of 5 to 8 Gy are more frequently used than fractionated doses, and similar results are found when

preoperative and postoperative treatments are compared [1]. Radiation therapy has been used successfully after heterotopic bone resection in patients with traumatic brain injury and spinal cord injury to help prevent recurrence and for local treatment of heterotopic ossification in spinal cord injury [2,16,17,35]. Pulse low-intensity electromagnetic therapy uses magnetic fields to improve blood flow to the target area and has been shown in one study to prevent the formation of heterotopic ossification after spinal cord injury [30,36].

Surgery

Although heterotopic ossification may recur after surgical resection, it remains the only definitive treatment for mature heterotopic bone. In fact, surgical excision is the most common treatment of heterotopic ossification after traumatic brain injury [29]. Surgical indications include joint immobility causing difficulty in activities of daily living, ankylosed joints leading to pressure ulcers or skin breakdown, and conditions in which heterotopic ossification contributes to focal peripheral neuropathy [2]. Preoperative planning often requires three-dimensional computed tomography and magnetic resonance imaging to assess the relationship between heterotopic bone and neurovascular structures at risk. Careful dissection with isolation of neurovascular bundles reduces risk of morbidity associated with hemorrhage, sepsis, or repeated ankylosis [2]. Functional range of motion can typically be reached with a wedge resection of the ectopic bone [2].

Controversy exists as to the timing of the procedure because bone maturity is difficult to assess. It has been shown that immature heterotopic bone has a greater incidence of recurrence [16,27]. Traditionally, three-phase bone scan and ALP levels have been used to monitor bone maturity. However, because both may remain abnormal indefinitely, many clinicians no longer wait for normalization of bone scans and ALP levels to proceed with resection [16]. Still, it is not uncommon for surgery to be delayed for up to 2 to 2.5 years in patients with traumatic brain injury or spinal cord injury; however, the suggested optimal timing is 12 to 18 months [29,37]. After heterotopic bone resection, radiation therapy and NSAIDs are often used to prevent recurrence [2,8].

Potential Disease Complications

Heterotopic bone deposition impairs normal joint range of motion and causes secondary soft tissue contractures, which involve surrounding skin, muscles, ligaments, and neurovascular bundles [2]. The resulting restrictive position predisposes the patient to the development of pressure ulcers and subsequent infections. Direct pressure or chronic spasticity can cause nerve ischemia and compression, resulting in focal peripheral neuropathy [2]. Vascular compression, deep venous thrombosis, and lymphedema may also result. Decreased range of motion predisposes to osteoporosis and subsequent pathologic fracture during transfer or lifting of the patient [2].

Potential Treatment Complications

NSAIDs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. There is also a

risk of defective bone-prosthesis union and poor bone healing in orthopedic populations when NSAIDs are used for the prevention of heterotopic ossification [8,31].

EHDP is generally a safe method for treatment of heterotopic ossification. The most common side effects are nausea and diarrhea. Twice-daily divided dosing of EHDP helps alleviate these symptoms. EHDP also carries a potential risk of bone fracture secondary to osteomalacia; if it is withdrawn after a short treatment duration, a rebound ossification secondary to prolonged osteoclast inhibition may result [10,32].

Radiation therapy is rarely associated with malignant neoplasia and does not disrupt wound healing, provided wounds are not in the field of irradiation [8,38]. In orthopedic populations after total hip arthroplasty, increased rates of trochanteric nonunion have been described with both high-dose fractionated and single-dose protocols [31,38].

Surgical complications, which carry a high morbidity and are not uncommon, include hemorrhage, sepsis, wound infection, repeated ankylosis, and heterotopic bone recurrence [8,27]. Chronic pain and recurrent contracture may also result. The distorted anatomy in heterotopic ossification makes dissection visibility difficult, endangering neurovascular structures [2]. Postoperative blood loss requiring transfusion is not uncommon despite good surgical hemostasis [2].

I97.2 Postmastectomy lymphedema syndrome
I89.0 Lymphedema, not elsewhere classified, praecox and secondary
Q82.0 Hereditary lymphedema

Definition

Between 3 and 5 million people in the United States suffer from lymphedema, which in a significant number develops from cancer and its treatment [1]. The incidence of post-mastectomy lymphedema ranges from 6% to 48%, depending on whether the patient received axillary radiation and surgery; if only lumpectomy is performed, the incidence drops to only 6%. This increases to 23% with use of

sentinel node biopsy and radiation therapy; but if axillary lymph node dissection and radiation therapy are used, the incidence is even higher at about 35% to 48% [1].

About 80% of lymphedema cases involve the lower limbs and relate to peripheral vascular disease [1]. Cervical cancer, melanoma, and pelvic cancers increase the frequency of secondary lymphedema of the lower extremity. An incidence of 21% to 49% is reported after cervical cancer surgery and radiation therapy. In women with endometrial cancer, 11% developed lower limb lymphedema after surgery and radiation therapy. Around the world, infection in the form of filariasis is the most common cause of lymphedema. An estimated 15 million people present with lower extremity lymphedema in filariasis-endemic regions in the world [2].

Lymphedema is a condition of an abnormal enlargement of part of the body associated with lymphostasis from dysfunction of the lymphatic system (Fig. 131.1). The dysfunction is due to the abnormal morphology of the lymphatic system, high production of lymph, or blockage in drainage [3,4]. The lymphatic system consists of vessels with lymph traveling through lymph nodes. The lymphatic vessels transport fluid, plasma proteins, and other substances from the tissue back into the circulatory system. Lymphedema results from the inability to drain the lymphatic fluid and the accumulation of it in the limb. Chronic edema initiates a cascade of events that cause transformation of the tissue with skin thickening, fibrosis, deposition of fat, and unhealthy skin changes after months to years. A classification of lymphedema includes primary (heritable) and secondary (acquired) causes [5]. Phlebolymphe-dema pertains to dysfunction of the lymphatic system in association with chronic venous insufficiency [6]. Chronic venous insufficiency is a manifestation of deep venous thrombosis, angiodysplasia, lack of valves in the venous system, or varicosities.

The radical excision of lymph nodes for malignant disease does not always cause lymphedema [7]. Lymphedema could occur as a late complication of surgery for malignant disease because of gradual failure, making the distal lymphatics pump harder through the most proximal damaged ducts over time. The body compensates by regenerating the transected lymphatics to some extent. With irradiation, fibrous scarring forms, increasing the risk of lymphedema. The diagnosis depends on the history and characteristic changes of the skin on clinical examination (Fig. 131.1).

FIGURE 131.1 Abnormal skin changes in the patient with lymphedema.

Symptoms

The hallmark of lymphedema is painless swelling. Although many people believe that pain is a major component of lymphedema, this is not typically present, especially in the early stages. One of the first symptoms of lymphedema is tightness of the cutis and subcutis [8]. Chronic indolent swelling of a limb is the most common presentation of lymphedema. Patients may complain that the arm feels heavy or that rings feel tight. Hypertrophy of fatty tissue occurs and eventually fibrosis too. In true lower extremity lymphedema, the feet are involved. The skin condition changes from being soft initially to becoming harder over time. Early or postsurgical lymphedema can spread proximally, an unusual finding after the first year, and lasts about 3 months after surgery [7].

Physical Examination

The patient with limb edema requires a thorough physical examination before the initiation of therapy. Swelling of a limb with or without pain may be the presentation of an infection, deep venous thrombosis, or obstruction caused by a tumor at the level of the lymph nodes. Limb temperature and discoloration should be noted. In early stages, the edema is pitting, but as lymphedema progresses, the edema becomes nonpitting. In the absence of treatment, distal enlargement of the wrist or ankle occurs. A discrepancy of 2 cm in circumference or a difference of 200 mL in volume from side to side has been accepted for the diagnosis of lymphedema. A multitude of skin changes occur over time (Table 131.1) [9]. Signs of lymphedema progression in-

clude a cool limb, skin thickening, limited range of motion, increased presence of papillomas, mycosis, and bacterial infection. Infection, such as cellulitis, erysipelas, and lymphangitis, must be recognized to prevent systemic malaise and worsening of the swelling [3].

Staging of the condition helps assess progression and evaluate better treatment options. Stages of lymphedema are as follows:

Stage 0 Preclinical: there is no swelling, and it can last months or years.

Stage I Reversible stage: swelling is soft and pitting.

Stage II Spontaneously irreversible stage: increased swelling and change in tissues with fibrosis formed.

Stage III Lymphostatic elephantiasis: limb becomes extremely swollen with thickened skin.

Lymphedema does not cause neurologic deficits, but paresthesias and numbness may occur in the same distribution of the edema. Explanations include coexistence of neurologic damage from node dissection, peripheral nerve injury, plexopathy, and chemotherapy-induced polyneuropathy. The possibility of cancer recurrence must be ruled out with imaging, such as computed tomography or magnetic resonance imaging with contrast enhancement.

Lipedema can occur with lymphedema. This is an abnormality of the deposition of fat involving the lower body, most commonly in women, of symmetric appearance. Swelling starts at the waist and finishes at the ankles without inclusion of the feet as opposed to lymphedema, in which the feet are involved. Lipedema does not respond to dietary intervention or complete decongestive therapy. If underlying hormonal imbalance exists, correction will improve this condition, and although it is controversial, liposuction can improve it in some cases [10,11].

Unilateral or bilateral venous insufficiency may be manifested with varicosities, fibrosis, thickened cutis, and brownish skin discoloration. Superimposed venous ulcers may occur in advanced cases [3,7].

Functional Limitations

Impaired mobility due to the excessive weight of the limb may occur in severe cases (Table 131.2) [4]. Tight clothing, restriction of movement, and loss of body image and self-esteem are frequent complaints leading to psychosocial impairment. Women with breast cancer-related lymphedema report problems with their sexual well-being and social interaction [12]. In the past, avoidance of physical activity was the norm for fear of worsening the edema. This has changed with new evidence supporting the benefits of physical activity and exercise [12]. Wearing of a compression garment during exercise is advised (Fig. 131.2).

Diagnostic Studies

The diagnosis of lymphedema is based on the history, physical examination, and noninvasive diagnostic procedures. New-onset lymphedema should be a diagnosis of exclusion after deep venous thrombosis and malignant disease (including cancer recurrence) are ruled out. Therefore, most patients with new-onset lymphedema will have a workup for malignant disease as well as a Doppler ultrasound examination to rule out deep venous thrombosis. The diagnosis can be confounded with conditions such as obesity, chronic venous insufficiency, occult trauma, fracture, and repeated infections. Genetic testing may be necessary if gene therapy becomes clinically viable in the future [13]. Currently, research with animal models is targeting the vascular endothelial growth factor receptor 3 (VEGFR-3) and its primary ligands (VEGF-C and VEGF-D), looking for potential molecular treatment strategies.

Differential Diagnosis of Chronic Edema [7]

SYSTEMIC ETIOLOGY

Congestive heart failure
Renal failure
Hypoalbuminemia
Protein-losing nephropathy
Myxedema

LOCAL ETIOLOGY

Primary or secondary lymphedema
Lipedema
Deep venous thrombosis
Chronic venous disease
Ipsilateral surgery
Cellulitis
Baker cyst
Cyclic or idiopathic edema
Tumor recurrence

Treatment

Initial

The risk of lymphedema can be reduced by use of sentinel node biopsy as part of the treatment for malignant neoplasms [14]. Early lymphedema may revert with appropriate compression of the limb and by maintaining an active lifestyle. The goals of the initial treatment include reduction of swelling, arrest of progression, improvement of other related symptoms, avoidance of infection, and optimization of function and quality of life. Treatment includes conservative, surgical, pharmacologic, and alternative methods.

The most commonly used drugs are the diuretics. However, diuretics are believed to worsen other types of lymphedema because they increase urination and produce hemoconcentration of tissue proteins. Because the edema is protein rich, the diuretic prompts protein to remain stagnant in the congested area, leading to fibrosclerosis. Diuretics may be used in the presence of ascites or hydrothorax. A short course of diuretics can help in the presence of malignant lymphedema [4].

Benzopyrones may increase the number of macrophages that hydrolyze tissue proteins to facilitate the removal of protein. Their exact mechanism of action is not well understood, the benefits remain unproven, and the use is limited because of the potential for liver toxicity [3]. Selenium, a free radical scavenger, reportedly has an antiedematous effect that potentiates the effect of complete decongestive therapy and reduces the risk of erysipelas infections in patients with lymphedema [15].

Antiseptic dressings for minor wounds and the early use of antibiotics for infections can prevent long-term complications. Prophylaxis with antibiotics such as phenoxymethylpenicillin (500 mg daily) is recommended for cases with recurrent cellulitis [3].

Rehabilitation

Treatment outcomes are most favorable with diagnosis and treatment early before fibrosis and hardening of the tissue occur. When pitting edema exists, the lymphedema is more responsive to treatment [16]. Complete decongestive therapy, the standard of care for lymphedema, is a multifaceted treatment approach performed by a certified lymphedema therapist that consists of two phases.

Phase one is the reductive phase. During this phase, manual lymphatic drainage, a technique similar to a gentle light touch massage that stimulates the lymphatics and facilitates drainage of congested areas, is used. Compression bandages employ multiple layers of short-stretch bandages and other materials, such as foam padding, to create a bandage with a low resting pressure and a high working pressure in the affected limb. Remedial exercises are movements with light exertion and stretches done while compression bandages or garments are worn. These exercises stimulate the lymph drainage into the thoracic duct [17]. Finally, meticulous skin and nail care requires moisturizing with a low-pH lotion; this prevents skin from drying and cracking and also discourages the growth of bacteria and fungus, which can cause infections and wounds. The initial phase of complete decongestive therapy ends when the maximum

volume reduction is achieved and there is no further improvement. Relative contraindications to institution of complete decongestive therapy include acute infections, cardiac edema, peripheral arterial occlusive disease, renal dysfunction, and acute deep venous thrombosis. Recurrent tumor should be treated before the use of massage (manual lymphatic drainage).

During phase two, or the maintenance phase, the patient is fitted with a compression garment to wear during the day and taught how to continue bandaging at night or to apply a nighttime compression device [17]. The patient may also be taught self-drainage of lymph or the use of an intermittent pneumatic compression device. The use of the intermittent pneumatic compression device is controversial, and there are concerns that a high-pressure single chamber may cause damage to superficial structures, edema in the trunk or genitals, and development of a fibrosclerotic ring above the device sleeve. In response to some of the concerns, the latest models have multichambers, with sequential pressure delivery, programmable pressures, and truncal clearance [18]. In this phase, it is important that the patient continue to take care of the skin and perform the home exercise program. Weight reduction has been proved to have a positive impact by reducing limb volume [19].

Studies have shown some success when other modalities are included together with complete decongestive therapy. For example, low-level laser therapy was approved by the Food and Drug Administration in 2006 for professional treatment and self-treatment of lymphedema. Studies have shown moderate to strong evidence for the effectiveness of low-level laser therapy [20]. Kinesio tape is widely used to treat edema and may be an alternative to short-stretch bandaging for breast cancer-related lymphedema when compliance with short-stretch bandaging after 1 month of intervention is poor [21]. Kinesio tape in conjunction with compression may improve results but has yet to be sufficiently studied. Oscillation therapy involves the use of electrostatic impulses to create a kneading effect to promote lymphatic drainage [22].

Surgery

Surgical options can benefit a few patients when the size of the limb interferes with mobility. Surgical procedures are still controversial. These are debulking procedures to remove excess tissue overgrowth; microsurgery to restore lymphatic continuity by use of a lymphatic collector or vein segment, also known as lymphaticovenous anastomosis [23]; and liposuction when lymphedema is nonresponsive to conservative management from the excess fat overgrowth. Patients still need to wear compression garments long term [24].

The standard of care in the past was to excise all of the regional lymph nodes during cancer surgery, but this is no longer the case to prevent morbidity such as lymphedema. For example, in breast cancer patients, sentinel lymph node dissection is associated with lower incidence of lymphedema than axillary lymph node dissection is. Sentinel lymph node dissection facilitates the resection of the sentinel node that combined with frozen-section histologic examination prevents unnecessary secondary surgeries, prevents lymphedema, and improves disease-specific survival [25].

Potential Disease Complications

Recurrent cellulitis and infections with staphylococcal resistant bacteria may occur. Delay in treatment increases the risk of sepsis. If it is untreated, lymphedema may progress to fibrosclerosis of the tissue and elephantiasis. A rare complication is lymphangiosarcoma, a malignant neoplasm in a lymphedematous limb described in post-mastectomy lymphedema and congenital lymphedema [7]. Stewart-Treves syndrome was first described in women who had undergone a radical mastectomy with subsequent lymphedema and lymphangiosarcoma.

Potential Treatment Complications

Potential complications include disease progression, liver complications from the use of benzopyrones, and worsening of lymphedema after liposuction from disruption of the remaining lymphatics.

 G12.21 Amyotrophic lateral sclerosis, progressive spinal muscle atrophy

G12.20 Motor neuron disease, unspecified

G12.22 Progressive bulbar palsy

G12.29 Other motor neuron disease, primary lateral sclerosis

Definition

The term *motor neuron disease* encompasses a heterogeneous group of progressive neuromuscular disorders characterized by the selective loss of upper or lower motor neurons. However, motor neuron disease is also used interchangeably with *amyotrophic lateral sclerosis* (ALS), which can be confusing for the uninitiated. ALS is the most common adult motor neuron disease. For the diagnostic criteria for ALS to be met, both upper and lower motor neuron involvement is necessary [1,2]. In sporadic cases with only lower motor neuron dysfunction, the disease is called progressive muscular atrophy; if upper motor neuron dysfunction is singularly present, it is primary lateral sclerosis; and if dysfunction is localized to the bulbar region, the disease is called progressive bulbar palsy. Most patients initially diagnosed as having progressive muscular atrophy, primary lateral sclerosis, or progressive bulbar palsy eventually progress to meet diagnostic criteria for ALS [3]. Those who do not convert have a slower rate of disease progression. This chapter focuses on ALS as the management principles are similar for the entire class of motor neuron diseases.

The prevalence of ALS is about 6 to 8 per 100,000 people, with an annual incidence of approximately 2 cases per 100,000 people. Men are more commonly affected than women, with a ratio nearing 2:1. Most cases of ALS are sporadic, having unknown etiology. Only 5% to 10% of patients have familial ALS, which is most commonly transmitted in an autosomal dominant fashion. Approximately 30% to 40% of familial cases in the United States and Europe are caused by mutations in the *C9orf72* gene; 20% worldwide are caused by mutations in the *SOD1* (superoxide dismutase) gene; and rarer forms of familial ALS have been linked to mutations in the *TARDBP*, *FUS*, *ANG*, *ALS2*, *SETX*, and *VAPB* genes [4,5]. Other inherited adult motor neuron diseases are Kennedy disease (X-linked recessive) and adult spinal muscular atrophy (autosomal recessive), which are purely lower motor neuron disorders with greatly increased life span compared with ALS.

ALS causes rapid, progressive skeletal muscle weakness and atrophy, leading to premature death by respiratory failure. Weakness begins in a focal region, such as a single limb, the bulbar muscles, or the respiratory muscles, and spreads to affect other regions. Extraocular muscles and bowel and bladder sphincter function are often spared until late in the disease course. Mean age at onset is the mid-50s, but ALS may develop in adults of any age. Rare juvenile familial forms exist with onset before the age of 25 years. Mean survival, without tracheostomy, is 3 years from diagnosis but ranges from less than 1 year to more than 20 years. One explanation for this extreme variability is that ALS is multiple disorders without a single etiology but rather with multiple causes, sharing a common final step in the pathophysiologic pathway—motor neuron apoptosis. This is illustrated by the varying phenotypes associated with familial forms of ALS [3]. Theories about the pathogenesis of sporadic ALS have implicated RNA toxicity, glutamate excitotoxicity, oxidative stress, neuroinflammation, protein misfolding, glial cell activation, and mitochondrial dysfunction, to name a few [5].

Symptoms

Early symptoms of ALS can be subtle and include muscle twitching and cramping, weakness, and loss of coordination. Patients with a predominantly upper motor neuron syndrome often present with muscle stiffness, weakness, loss of dexterity, and loss of voluntary motor control from spasticity that may affect vocal quality or limb function. Patients with a predominantly lower motor neuron syndrome may present with weakness and muscle atrophy, fasciculations, muscle cramps, and flaccid dysarthria. Bulbar symptoms include dysarthria, dysphagia, sialorrhea (drooling), and pseudobulbar affect—laughing or crying in exaggeration of or incongruent with mood. Symptoms are initially painless and asymmetric across limbs. As the disease relentlessly progresses, weakness and atrophy spread to affect all skeletal muscles, causing significant impairment and disability. If patients do not succumb first to respiratory failure, they will ultimately transition from independent function to total dependence.

Respiratory failure is the presenting symptom in a rare few. Constitutional symptoms of weight loss and generalized fatigue are common. Cognitive symptoms including behavioral or executive dysfunction have been reported to occur in 33% to 51% of patients [6]. Most have milder symptoms; approximately 5% to 14% meet clinical criteria for a diagnosis of frontotemporal dementia [6].

Physical Examination

Physical examination of a patient with suspected motor neuron disease should be aimed at establishing the certainty of diagnosis. ALS is diagnosed clinically, and the patient with suspected motor neuron disease requires a thorough neurologic examination, assessing each of the four major body regions (bulbar, cervical, thoracic, and lumbar) for signs of upper and lower motor neuron involvement. The “gold standard” for the diagnosis of upper motor neuron disease is establishment of the presence of pathologic reflexes—a brisk jaw jerk, Hoffmann sign, abdominal skin reflex, and Babinski sign. Increased muscle stretch reflex responses as demonstrated by increased spread and amplitude or clonus are considered pathologic. Reflexes that would be graded normal but are

elicited from atrophied and weak muscles should also be considered pathologic. Evidence of lower motor neuron disease includes muscle weakness, atrophy, hypotonia, hyporeflexia, and fasciculations. Patients with ALS may be hyperreflexic and hyporeflexic, depending on the stage at which they are in the disease process and whether they have a predominance of upper or lower motor neuron phenotype. For example, hyperreflexia occurs in the patient with upper motor neuron dysfunction, but this sign can be overcome and silenced by concomitant lower motor neuron loss causing muscle atrophy and hyporeflexia. Because ALS is an asymmetric and spreading process, the upper motor neuron signs may be more predominant than the lower motor neuron signs, or vice versa, within any single limb or between limbs and body regions. These examination findings will change over time as the disease progresses. The tongue should be examined for fasciculations, atrophy, strength, and range of motion. The patient’s mental status, nonmotor cranial nerve function, sensory examination, and cerebellar examination findings are usually normal.

In patients with an established diagnosis, the physical examination documents disease progression and includes the musculoskeletal and cardiorespiratory systems in addition to the neurologic evaluation. The musculoskeletal examination focuses on assessment of range of motion and evaluation of painful joints or soft tissue structures. Because progressive respiratory failure is a ubiquitous manifestation of ALS, follow-up appointments should be scheduled regularly (i.e., every 3 months) and the cardiorespiratory system assessed at each visit. Forced vital capacity (FVC) and maximal inspiratory, maximal expiratory, and peak cough pressures can be measured with a spirometer in the office setting and should be considered part of the regular cardiorespiratory follow-up evaluation, providing relevant information for clinical decision-making and prognosis (Table 132.1).

Table 132.1 Pulmonary Function Testing in Amyotrophic Lateral Sclerosis

Measure	Key Values	Significance
Forced vital capacity	<75% of predicted at time of diagnosis [49]	Poor prognostic indicator
	Slower rate of monthly decline (<3.1%/month) [50]	Predicts slower disease progression
	50% of predicted [37]	Meets Medicare guidelines for initiation of noninvasive ventilation
Maximal inspiratory pressure	−60 cm H ₂ O [37]	Meets Medicare guidelines for initiation of noninvasive ventilation
Maximal expiratory pressure	Normal value [50]	Associated with 2-year survival
	Abnormal value	Associated with abnormal cough
Peak cough flow	270 L/min [37]	Initiate mechanical cough assistance
Sniff nasal inspiratory pressure	−40 cm H ₂ O [37]	Meets Medicare guidelines for initiation of noninvasive ventilation

Functional Limitations

The pattern of progressive functional limitation is directly related to the patient's motor neuron disease phenotype. Bulbar-onset ALS initially affects the patient's ability to speak and to swallow and typically spreads to involve the muscles of the upper extremities before the lower extremities [7]. These patients have a difficult time maintaining their weight both because of dysphagia and because of the loss of upper limb strength that impairs their ability to feed themselves. Eventually, bulbar-predominant patients become anarthric with accompanying severe dysphagia that limits their ability to control their secretions and to swallow their own saliva.

The functional limitations that develop in patients with spinal-onset ALS are the direct or indirect result of muscle weakness and atrophy. In lumbar spine onset, gait is abnormal early in the disease secondary to footdrop or hip flexion weakness. As the disease progresses, the patient's mobility worsens. Eventually, even the most basic activities of daily living become impossible to perform. Patients often transition quickly from independence to total dependence.

Reactive depression, generalized fatigue, and musculoskeletal pain may further limit function.

Diagnostic Studies

The diagnosis of ALS is based on the combined clinical and electrodiagnostic examinations. Neuroimaging and clinical laboratory studies are used to exclude other conditions that mimic ALS. All patients thought to have a motor neuron disease should undergo electrodiagnostic testing. The Awaji-shima

revised El Escorial criteria (Table 132.2) are used to establish the certainty level of the diagnosis of ALS [1,2]. These criteria were developed as a tool for clinical trial enrollment but are commonly used in the clinic. The revised criteria classify the certainty level of diagnosis into one of three categories: definite, probable, and possible, which no longer includes the categories of Suspected ALS or Probable ALS Laboratory Supported that were part of the El Escorial criteria (Fig. 132.1). In addition to both upper and lower motor neuron findings, a diagnosis of ALS requires evidence of progressive spread of signs or symptoms within a single body region or from one of the four body regions to another. Certainty level of diagnosis depends on how many regions reveal upper motor neuron and lower mo-

Table 132.2 Awaji-shima Revised El Escorial Criteria: Clinical Certainty Levels for the Diagnosis of Amyotrophic Lateral Sclerosis [1]

Clinical Certainty	Clinical or Electrophysiologic Evidence
Clinically definite	UMN and LMN findings in at least three body regions
Clinically probable	UMN and LMN findings in at least two body regions with UMN findings rostral to LMN findings
Clinically possible	UMN and LMN findings in one body region, or UMN findings in at least two body regions without LMN findings, or LMN findings that are rostral to UMN findings

LMN, lower motor neuron; UMN, upper motor neuron. Four body regions: bulbar, cervical, thoracic, lumbar.

tor neuron disease [1]. Electrophysiologic findings of denervation, including positive sharp waves, fibrillation potentials, and fasciculation potentials, are used to confirm lower motor neuron dysfunction in clinically affected regions and to detect subclinical lower motor neuron dysfunction, thereby extending the clinical examination. Signs of denervation observed during electromyography are now considered equivalent to lower motor neuron symptoms on clinical examination [1].

Imaging studies are used to exclude possibilities other than motor neuron disease from the differential diagnosis. Magnetic resonance imaging is the primary imaging modality in the evaluation of patients with suspected ALS. Almost all patients should have magnetic resonance imaging of the cervical spine to exclude cord compression, syrinx, or other spinal cord disease. The location of symptoms will dictate whether other regions of the spinal cord should be imaged. In those presenting with bulbar symptoms, brain magnetic resonance imaging should be performed to exclude stroke, tumor, syringobulbia, and other pathologic processes.

In most neuromuscular clinics, a routine panel of laboratory tests is performed for all patients thought to have ALS. A suggested set of such tests is provided in Table 132.3. The rationale behind the performance of this extensive battery of tests is to assess the general health of the patient and to exclude treatable conditions. The differential diag-

nosis, developed after the history and physical examination, may suggest that more specialized testing be performed. Table 132.4 suggests additional tests that may be warranted when the presentation is atypical with a progressive muscular atrophy, primary lateral sclerosis, or progressive bulbar palsy phenotype. When there is a family history of motor neuron disease, genetic testing may be considered.

Table 132.4 Specialized Laboratory Testing

Phenotype	Test	Diagnosis Excluded
Progressive muscular atrophy	DNA test: CAG repeat on X chromosome	Kennedy disease
	DNA test: <i>SMN</i> gene mutation	Spinal muscular atrophy
	Hexosaminidase A	Hexosaminidase A deficiency (heterozygous Tay-Sachs disease)
	Voltage-gated calcium channel antibody test	Lambert-Eaton myasthenic syndrome
Primary lateral sclerosis	Cerebrospinal fluid examination	Polyradiculopathy, infectious or neoplastic
	GM ₁ antibody panel	Multifocal motor neuropathy
	Very long chain fatty acids	Adrenoleukodystrophy
	Human T-lymphotropic virus 1 (HTLV-1) antibodies	HTLV-1 myelopathy (tropical spastic paraparesis)
Progressive bulbar palsy	Parathyroid hormone	Hyperparathyroid myelopathy
	Cerebrospinal fluid examination	Multiple sclerosis
	Acetylcholine receptor antibodies	Myasthenia gravis
	DNA test: CAG repeat on X chromosome	Kennedy disease
	Cerebrospinal fluid examination	Multiple sclerosis

Differential Diagnosis

The differential diagnosis varies on the basis of phenotype and is stratified by lower motor neuron, upper motor neuron, bulbar, or mixed lower and upper motor neuron involvement.

LOWER MOTOR NEURON ONLY

Progressive muscular atrophy
Spinal muscular atrophy
Kennedy disease
Poliomyelitis, postpoliomyelitis syndrome
Benign monomelic amyotrophy
Hexosaminidase A deficiency
Polyradiculopathy
Multifocal motor neuropathy with conduction block
Chronic inflammatory demyelinating polyneuropathy
Motor neuropathy or neuronopathy
Lambert-Eaton syndrome
Plexopathy
Benign fasciculations

UPPER MOTOR NEURON ONLY

Primary lateral sclerosis
Multiple sclerosis
Adrenoleukodystrophy
Subacute combined systems degeneration
Hereditary spastic paraparesis
Myelopathy
Syringomyelia

BULBAR

Progressive bulbar palsy
Myasthenia gravis
Multiple sclerosis
Foramen magnum tumor
Brainstem glioma
Stroke
Syringobulbia
Head and neck cancers
Polymyositis
Oculopharyngeal muscular dystrophy
Kennedy disease

UPPER AND LOWER MOTOR NEURONS

Familial or sporadic amyotrophic lateral sclerosis
Cervical myelopathy with radiculopathy
Syringomyelia
Spinal cord tumor or arteriovenous malformation
Lyme disease

Treatment

Initial

Pharmacologic

There is no cure for ALS; however, ongoing research is focused on identifying disease mechanisms and finding drugs to slow disease progression. Riluzole (Rilutek) is the only medication approved by the Food and Drug Administration (FDA) specifically for treatment of ALS. It is an antiglutamate agent that was approved by the FDA for treatment of ALS in 1995 after two clinical trials showed that the drug slowed disease progression [8,9]. A Cochrane review reporting a meta-analysis of riluzole clinical trials showed a survival benefit of approximately 2 months [10]. Unfortunately, no functional benefit was derived as strength declined at a rate similar to that in those taking riluzole and placebo. The recommended dose of riluzole is 50mg twice daily. The most common adverse side effects are fatigue, nausea, and elevation of hepatic enzymes. Riluzole is contraindicated in those with hepatic enzyme activity of more than five times the upper limit of normal.

Offering patients pharmacologic treatment of their disease and access to clinical trials has psychological benefits that may outweigh the actual slowing of disease progression currently able to be achieved. The following is an abbreviated list of compounds and biologics that are currently in clinical trial for ALS: arimoclomol, creatine combined with tamoxifen, edaravone, neural stem cells, and mesenchymal stem cells. Negative ALS clinical trials have tested many therapeutics and supplements, including multiple growth factors, dexamipexole, creatine, lithium, ceftriaxone, glutamate antagonists, anti-inflammatory agents (celecoxib), calcium channel blockers, and amino acids [11]. Whereas many ALS patients take multiple supplements, no double-blind, placebo-controlled trials

Table 132.5 Pharmacologic Management of Amyotrophic Lateral Sclerosis–Related Symptoms

Symptom	Potential Therapy
Pseudobulbar affect	Amitriptyline, selective serotonin reuptake inhibitors, Nuedexta (dextromethorphan hydrobromide 20mg/quinidine sulfate 10mg)
Sialorrhea	Glycopyrrolate (Robinul), amitriptyline, atropine 0.5% sublingual drops, scopolamine transdermal patch, botulinum toxin, radiation therapy
Thick secretions Spasticity	Guaifenesin, beta blocker Oral or intrathecal baclofen, tizanidine, regional botulinum toxin injection
Laryngospasm	Treat underlying gastroesophageal reflux: proton pump inhibitors (omeprazole), H ₂ receptor blockers (ranitidine)
Cramps Depression	Mexiletine, stretching Tricyclic antidepressants, selective serotonin reuptake inhibitors
Anxiety Fatigue Insomnia	Lorazepam, buspirone Modafinil Address nocturnal hypoventilation first; amitriptyline, zolpidem, trazodone
Urinary urgency Constipation	Oxybutynin, amitriptyline Increased hydration, fiber supplements (Metamucil), osmotics (MiraLax), saline laxatives (milk of magnesia), stool softeners (Colace), stimulants (Dulcolax), enemas

have proved their efficacy. In the future, a cocktail approach to slowing of disease progression may be the ideal treatment strategy [12].

Symptomatic

A number of drugs are useful for treatment of spasticity, sialorrhea, pseudobulbar affect, depression, and anxiety (Table 132.5).

Spasticity requires treatment only if it interferes with function. Nonpharmacologic management involves teaching patients stretching exercises and positioning techniques that decrease muscle tone. Baclofen (Lioresal) is the most effective pharmacologic agent, followed by tizanidine (Zanaflex). Diazepam (Valium) should be avoided because it may suppress respiration, and dantrolene (Dantrium) is not recommended because it causes excessive muscle weakness. In general, pharmacologic management of spasticity is less successful in ALS than in multiple sclerosis or spinal cord injury because the lower motor neuron component of ALS makes patients extremely susceptible to the development of excessive weakness.

Patients with bulbar dysfunction experience sialorrhea because they have difficulty swallowing and managing the oral secretions they normally produce. A variety of anticholinergic drugs may be used to dry the mouth. Tricyclic antidepressants are often tried first but may not be tolerated because of adverse side effects (excessive dry mouth, somnolence, urinary retention). One benefit of the tricyclic antidepressants is that they may treat other ALS-related symptoms,

such as pseudobulbar affect, insomnia, and pain. Tricyclic antidepressants are contraindicated in patients with cardiac arrhythmia or conduction disorder. When tricyclic antidepressants are not tolerated, a scopolamine patch (Transderm Scop) or glycopyrrolate (Robinul) may be helpful. If these treatments are inadequate, patients may benefit from salivary gland botulinum toxin injection [13–15].

Pseudobulbar affect, sometimes called emotional incontinence, may become distressing for both the patient and the family. Amitriptyline (Elavil) or fluvoxamine (Luvox) may help blunt the intensity of these inappropriate or exaggerated reactions. A combination preparation of dextromethorphan and quinidine (Nuedexta) was found to be effective in a large randomized clinical trial [16] and was granted FDA approval in late 2010 for the treatment of pseudobulbar affect. Nuedexta is contraindicated in patients with heart failure, long QT syndrome, and conduction block.

Reactive depression and anxiety are both normal responses to a diagnosis of ALS [17]. Patients and their families may benefit from individual counseling and participation in ALS support groups. Anxiety may be treated with benzodiazepines as long as the patient does not have significant reduction of vital capacity. Undetected hypoventilation may produce or contribute to preexisting feelings of anxiety. Depression should be treated pharmacologically because not treating it may have a significant negative impact on the quality of life remaining [18,19]. Selective serotonin reuptake inhibitors (SSRIs) are good first choices because of their minimal side effects. Tricyclic antidepressants may be preferred if they are also needed to treat other symptoms, such as sialorrhea or pseudobulbar affect. Caution should be taken in prescribing both an SSRI and a tricyclic antidepressant as SSRIs will increase the serum level of the tricyclic antidepressant and increase the potential for serious drug-related events.

Rehabilitation

Exercise

Skeletal muscle weakness is the primary impairment in ALS and causes the majority of the clinical problems. In the early stages of ALS, patients often inquire about the role of exercise in preventing or forestalling the development of weakness. There remains scarce evidence on which to base recommendations for exercise in ALS. Little research has been published since the 2008 Cochrane review of Dal Bello-Haas et al [20]. However, a search of www.clinicaltrials.gov identified two ongoing clinical trials, one studying the effects of resistance training in patients with ALS and the other studying aerobic exercise training [21]. Rehabilitation strategies later in the disease focus on augmenting function by compensating for muscle weakness to maintain independence.

Three forms of exercise training are most relevant to patients with ALS: flexibility, strengthening, and aerobic exercise. Flexibility training helps prevent the development of painful contractures, is considered first-line treatment of spasticity, and aborts painful muscle spasms. A home stretching program, designed by a knowledgeable therapist, is appropriate for the ALS patient throughout the course of the disease. The stretching routine initially may be created for independent performance but necessarily will be transi-

tioned to caregiver-assisted exercises when the patient is no longer capable of performing them alone.

Physicians caring for ALS patients have traditionally been reluctant to recommend strengthening exercises. The reasons for this appear to be twofold; epidemiologic studies have inconsistently suggested a link between high-intensity physical exercise and disease onset, and reports of overuse weakness accelerating disease progression have appeared in the literature [22,23]. This philosophy promotes the development of disuse weakness, compounding the disability produced by ALS itself. The literature supporting the development of overwork weakness in neuromuscular patients is anecdotal and has not been demonstrated in controlled prospective studies. A single randomized trial of strength training in ALS has been published [24]. It demonstrated a slowing of decline in physical function as measured by the ALS Functional Rating Scale out to 6 months after exercise initiation compared with the control group. No adverse effects were observed. Studies of patients with more slowly progressive neuromuscular diseases and postpoliomyelitis syndrome suggest that only muscles mildly affected by the disease process can be strengthened by a moderate-intensity resistance program [25–27]. Interested ALS patients should be encouraged to begin or to continue a resistance program to maximize the strength of unaffected or mildly affected muscles with the goal of prolonging function. Until further studies have been completed examining the effects of high-intensity strength training in ALS, resistance exercise can safely be accomplished by instructing the patient to use a weight that can be lifted 20 times in submaximal sets of 10 to 15 repetitions. This ensures that the training is performed at a low to moderate level of resistance. Common sense would suggest that if an exercise regimen consistently produces immediate or severe delayed muscle soreness or fatigue lasting longer than a half-hour after exercise, it is too strenuous and is impairing function. If the patient chooses to exercise, the level of postexercise fatigue and recovery time should be ascertained during the regular follow-up appointments. Recommendations for modification of exercise intensity and duration should be provided on the basis of the patient's response.

Aerobic exercise helps maintain cardiorespiratory fitness. A study of moderate aerobic activity in patients with ALS demonstrated a short-term positive effect on disability up to 3 months after exercise initiation compared with controls [28]. Multiple studies in transgenic mouse models of ALS have shown that aerobic exercise prolongs survival [29–31]. Given the lack of any apparent contraindication, aerobic exercise training is recommended for patients with ALS as long as it can be performed safely without a risk of falling or injury. In addition to the physical benefits, strengthening and aerobic exercise may have a beneficial effect on mood, psychological well-being, bone health, appetite, and sleep. Further studies are needed to assess the impact of regular exercise and varying exercise intensities on the patient with ALS.

Assistive Technology for Mobility

As ALS progresses, the rehabilitation focus shifts from exercise to maintenance of independent mobility and function for as long as possible. Interventions include assistive devices such as canes, walkers, braces, hand splints, wheelchairs, and scooters; home equipment such as dressing aids, adapted utensils, grab bars, raised toilet seats, shower

benches, and lifts; home modifications (ramps, wide doorways); and automobile adaptations, such as hand controls, environmental control units, and voice-activated software. These rehabilitation interventions are best provided by a multidisciplinary team that includes a physiatrist, physical therapist, occupational therapist, and orthotist.

Pain Management

Patients frequently have musculoskeletal pain syndromes, such as adhesive capsulitis (frozen shoulder), low back pain, and neck pain due to muscle weakness and inability to change positions. Measures to prevent adhesive capsulitis include range of motion exercises and adequate support for a hypotonic arm rather than allowing it to dangle at the patient's side. Low back pain can be triggered by an ill-fitting seating system. Preventive measures include a lumbar support for the wheelchair, a good cushion on a solid seat, the encouragement of frequent weight shifts, and a reclining back and tilt-in-space wheelchair. Neck pain associated with head drop is one of the most difficult musculoskeletal pain issues to remedy. A variety of cervical collars may be tried, but a head support on the wheelchair or a reclining lounge chair may be more comfortable than a collar. Nonpharmacologic measures such as massage and transcutaneous electrical nerve stimulation can also be used for pain control. Acetaminophen alone or combined with nonsteroidal anti-inflammatory drugs, lidocaine patches, or, if necessary, opioid medications can be used to alleviate musculoskeletal pain. The major concerns with opiate use are respiratory depression and constipation. The respiratory depression of opiates may be acceptable in the late and terminal stages of the disease when morphine is needed to relieve air hunger.

Dysphagia

Adequate swallowing function is necessary to maintain the nutritional status of the patient with ALS (unless a feeding tube is in place). If nutritional status is not properly maintained, patients tend to use muscle as fuel and thus lose muscle mass and strength earlier than they would otherwise [32]. Swallowing dysfunction may also precipitate aspiration pneumonia or respiratory failure. Early signs and symptoms of dysphagia are drooling, a wet voice, coughing during or after drinking thin liquids, nasal regurgitation, and requiring an excessive amount of time to complete meals. Patients should be referred to a speech pathologist when the first signs of dysphagia develop. Those with mild swallowing difficulties can be taught compensatory techniques to reduce the risk of aspiration and choking [33]. Recommendations may be given concerning modification of food consistencies. Feeding tube placement is indicated with the development of aspiration pneumonia, with loss of more than 10% of body weight, and when an excessive amount of time is required to eat such that quality of life is impaired.

Dysarthria

Early or mild dysarthria may be managed by having a speech therapist teach patients adaptive strategies, such as overarticulation and slowing of the speaking rate to avoid vocal fatigue. Speech therapy with the intent of improving speech quality has not been shown to be effective and is not indicated for ALS patients. In patients

with hypernasal speech caused by palatal weakness and primarily lower motor neuron dysfunction, a palatal lift or augmentation prosthesis may improve speech clarity [34]. As dysarthria worsens, patients require alternative forms of communication. Low-technology interventions include letter and word boards for written communication in those with good hand function. Higher technology solutions include iPad (Apple, Inc., Cupertino, Calif) voice applications and more traditional augmentative communication devices with a voice synthesizer (i.e., DynaVox, Pittsburgh, Pa; Tobii Technology, Stockholm, Sweden). As long as one muscle, somewhere in the body, can be voluntarily activated (including the extraocular muscles), the patient should be able to operate a communication device. High-technology solutions to communication problems are not suitable for all patients. The most enduring systems are flexible so that the method of access can be modified as weakness progresses.

Pulmonary Rehabilitation (see also Chapter 150)

Respiratory failure is the primary cause of death in ALS. In the absence of underlying intrinsic pulmonary disease, the respiratory failure in ALS is purely mechanical. Because of muscle weakness, the lungs do not inflate fully on inspiration. Most patients with ALS remain asymptomatic until the FVC is less than 50% of predicted. Pulmonary function tests, particularly the FVC, should be monitored every few months, depending on rate of disease progression. Nocturnal hypoventilation is typically the earliest manifestation of respiratory insufficiency; symptoms include poor sleep with frequent awakening, nightmares, early morning headaches, and excessive daytime fatigue and sleepiness [35]. Another early sign of respiratory muscle weakness is a weak cough and difficulty in clearing secretions.

The management of respiratory failure in ALS involves prevention of infection and provision of noninvasive or invasive mechanical ventilatory assistance. All patients with ALS should receive a yearly influenza vaccination and a pneumococcal vaccination with boosters every 5 years. Patients with an inadequate cough, as determined by a peak cough flow measurement of 270 L/min or less, can be helped by manually assisted coughing or an in-exsufflator device that mechanically augments the cough [35]. Providing patients with supplemental oxygen should typically be avoided as it may suppress respiratory drive, exacerbate alveolar hypoventilation, and ultimately lead to carbon dioxide retention and respiratory arrest [36]. Supplemental oxygen is recommended only for patients with a concomitant pulmonary disease or as a comfort measure for those who decline assisted ventilation. Noninvasive positive pressure ventilation (NIPPV) is considered standard of care for patients with ALS. The American Academy of Neurology's practice parameter on ALS recommends that NIPPV be introduced when the FVC falls to 50% of predicted or earlier if the patient is symptomatic [37]. However, others have suggested that earlier introduction of NIPPV may further improve survival and quality of life [38,39]. With good patient acceptance, NIPPV can extend the life of an ALS patient well beyond that of available disease-modifying medications.

NIPPV can be delivered through a variety of oral or nasal mask interfaces with use of bilevel positive airway pressure

machines or portable volume-cycled ventilators. Bilevel positive airway pressure is currently the most commonly used form of NIPPV. Gaining popularity are newer technologies that offer volume-assured pressure support and provide automatic inspiratory and expiratory pressure adjustments to meet the tidal volume or alveolar ventilation needs of patients with progressive restrictive lung disease. Initially, NIPPV is used at night. As FVC continues to decline, ventilator use can be extended into the day and eventually become continuous. Although studies have confirmed that use of NIPPV prolongs survival and may slow the decline of FVC [40,41], it is a temporary measure. Patients wishing to prolong their life to the fullest extent possible may consider invasive mechanical ventilation.

Discussion concerning respiratory failure should be initiated soon after the diagnosis of ALS is confirmed so that patients and their families can learn about their choices and, ideally, make a decision about invasive ventilator use in a noncrisis situation. These discussions should include both the benefits and limitations of invasive ventilation. An increasing number of patients are choosing tracheotomy and mechanical ventilation. In a recently published study, 31.3% of patients attending an ALS clinic chose mechanical ventilation with a median increase in survival of 16 months compared with nontracheostomized patients [42].

Before initiation of mechanical ventilation, patients should outline their wishes about withdrawal of treatment as part of an advance directive and inform their family and physicians; continued muscle atrophy and weakness may lead to a “locked-in” state in which patient communication is no longer possible. In one retrospective study, the most common reason for withdrawal of mechanical ventilation by ALS patients was a “loss of meaning in life.” [43]

Procedures

Management of Sialorrhea

Botulinum toxin injection of the salivary glands is the preferred method for management of sialorrhea in patients who do not respond to pharmacologic therapy [13–15]. Botulinum toxins A and B have been found to be equally effective. The safety of injection is increased with ultrasound guidance. Another treatment option for the patient refractive to more conservative treatments is radiotherapy of the parotid glands [44].

Gastrostomy Tube

A gastrostomy tube is recommended in ALS patients when they show signs of nutritional deficiency (i.e., lose 10% of their weight). The American Academy of Neurology’s practice parameter on ALS states that the morbidity and mortality of percutaneous endoscopic gastrostomy tube placement increase when the FVC falls below 50% of predicted [37] and recommends placement before that time. Some studies have shown that percutaneous endoscopic gastrostomy tubes can be safely placed with bilevel positive airway pressure assistance in patients with lower FVCs [45,46]. In addition, radiologically inserted gastrostomy tube placement appears to be safer, better tolerated in patients with ALS, and preferable in patients with low FVCs; less sedation is required, incidence of aspiration is lower, tube placement is

more often successful, and acute respiratory decompensation observed with percutaneous endoscopic gastrostomy is avoided [47,48].

Tracheostomy

Every effort should be made to have a tracheotomy performed on a planned basis after a patient has chosen to use invasive ventilation. However, this is often not the case, and the procedure is commonly performed during a crisis situation. Patients should be given early access to unbiased literature describing the procedure and reviewing care and cost considerations to enable an informed decision. Once it is placed, a cuffless tracheostomy tube or a tube with a deflated cuff is preferred.

Potential Disease Complications

Disease complications include progressive weakness, joint contractures, musculoskeletal pain syndromes, osteoporosis, fractures due to falls, dysphagia, dehydration, impaired nutrition, aspiration, dysarthria, depression, progressive respiratory failure, pneumonia, pressure wounds, deep venous thrombosis, and death.

Potential Treatment Complications

The potential treatment complications include drug reactions (e.g., to riluzole, tricyclic antidepressants) and misplacement, malfunction, or infection of the percutaneous endoscopic gastrostomy tube or radiologically inserted gastrostomy tube.

Complications of long-term ventilation by tracheostomy are tracheomalacia, pneumonia, loss of all skeletal muscle function including extraocular movements causing a locked-in state, and dementia.

CHAPTER 133

Movement Disorders

Kenneth H. Silver, MD

Synonyms

Extrapyramidal disease
Hypokinesias
Hyperkinesias
Dyskinesias

ICD-9 Codes

307.2 Tics
307.20 Tic disorder, unspecified
307.22 Chronic motor tic disorder
307.23 Gilles de la Tourette disorder
332 Parkinson disease
332.0 Parkinsonism or Parkinson disease:
primary, idiopathic
332.1 Secondary parkinsonism
Parkinsonism due to drugs
333.0 Other degenerative diseases of the
basal ganglia
Progressive supranuclear ophthalmoplegia
Shy-Drager syndrome
333.1 Essential and other specified forms of
tremor
333.2 Myoclonus
333.4 Huntington chorea
333.5 Other choreas
333.6 Idiopathic torsion dystonia
333.84 Organic writers' cramp
781.0 Abnormal involuntary movements:
abnormal head movements, spasms,
fasciculation, tremor

ICD-10 Codes

F95.9 Tic disorder, unspecified
F95.1 Chronic motor or vocal tic disorder

F95.2 Tourette's disorder
G20 Parkinson's disease
G21.9 Secondary parkinsonism, unspecified
G21.19 Other induced secondary parkinsonism
G23.9 Degenerative disease of basal ganglia,
unspecified
G23.1 Progressive supranuclear
ophthalmoplegia
G90.3 Multi-system degeneration of the
autonomic nervous system
G25.0 Essential tremor, familial
G25.3 Myoclonus
G10 Huntington's disease
G25.5 Chorea NOS
G24.1 Genetic torsion dystonia
G25.89 Other specified extrapyramidal and
movement disorders
R25.1 Tremor, unspecified

Definition

Involuntary movement disorders can be characterized by either too little (hypokinetic) or too much (hyperkinetic) movement. Hypokinetic problems include Parkinson disease and Parkinson-like conditions, such as progressive supranuclear palsy, vascular or trauma-induced parkinsonism, and multisystem atrophy (which encompasses the related disorders of Shy-Drager syndrome, striatonigral degeneration, and olivopontocerebellar degeneration). Hyperkinetic disorders include parkinsonian and nonparkinsonian tremor, tics, Gilles de la Tourette syndrome, dystonia, dyskinesias (including tardive dyskinesias), hemifacial spasm, athetosis, chorea (including Huntington disease), hemiballismus, myoclonus, and asterixis [1].

Essential tremor, the most common movement disorder, is 5 to 10 times more prevalent than Parkinson disease in the general population. Parkinson disease affects 1 million Americans including 1% of those older than 60 years. Idiopathic Parkinson disease constitutes approximately 85% of all the Parkinson-like conditions; neuroleptic-induced Parkinson disease (7%-9%), vascular parkinsonism (3%),

multisystem atrophy (2.5%), and progressive supranuclear palsy (1.5%) represent much smaller fractions. Relatively rare, Huntington disease occurs with a frequency in the population as low as 0.004% by some estimates [2,3].

Symptoms

Tremors, the most common form of involuntary movement disorders, are characterized by rhythmic oscillations of a body part. Tremors can be classified as to the situation in which they are most prominent, that is, most pronounced at rest or with movement. Tremors with movement are subdivided into those occurring with maintained posture (postural or static tremor, tested by holding the arms out in front), with movement from point to point (kinetic or intentional tremor, tested by finger to nose pointing), or with only a specific type of movement (task-specific tremor). Tremors that are at their worst at rest are exclusively associated with Parkinson disease or other parkinsonian states (such as those produced by neuroleptics) [2,4].

Parkinsonian patients commonly show a resting tremor, slowness of movement or bradykinesia, and a form of increased muscle tone called rigidity (see Chapter 141 for more details). Other common features are reduction in movements of facial expression resulting in “masked facies,” stooped posture, and reduction of the amplitude of movements (hypometria). Also seen are changes in speech to a soft monotone (hypophonia) and small, less legible handwriting (micrographia). Walking becomes slower, stride length is reduced, and pivoting is replaced with a series of small steps (turning “en bloc”) [5,6]. The nonmotor symptoms associated with Parkinson disease can be equally disabling: fatigue, pain, and neuropsychiatric disturbances, among others [3]. The following syndromes typically are manifested with the listed features in addition to the characteristic symptoms of Parkinson disease (tremor and rigidity) [7].

- Shy-Drager syndrome: autonomic failure with prominent postural hypotension
- Progressive supranuclear palsy: reduction in vertical gaze and slowing of eye movements
- Vascular parkinsonism: early dementia with brisk tendon reflexes
- Multiple head trauma, “parkinsonism pugilistica”: early dementia with brisk tendon reflexes
- Olivopontocerebellar degeneration: prominent intention tremor, imbalance, and ataxia

Tics are sustained nonrhythmic muscle contractions that are rapid and stereotyped, often occurring in the same extremity or body part during times of stress. The muscles of the face and neck are usually involved, with movement of a rotational sort away from the body’s midline. They are commonly familial and often seen in otherwise normal children between the ages of 5 and 10 years and usually disappear by the end of adolescence. Tourette syndrome is characterized by motor and vocal tics lasting for more than 1 year and may involve involuntary use of obscenities and obscene gestures, although such behavior may be mild and transient and occurs only in a minority of afflicted persons [6,8].

Dystonias are slow, sustained contractions of muscles that frequently cause twisting movements or abnormal postures. The disorder resembles athetosis but shows a more sustained static contraction. When rapid movements are involved, they

are usually repetitive and continuous. Dystonia often increases with emotional or physical stress, anxiety, pain, or fatigue and disappears with sleep. The dystonias are further classified as focal, segmental, or multifocal on the basis of the distribution of muscles affected. Symptoms of hemifacial spasm usually begin in the orbicularis oculi and later involve other muscles innervated by cranial nerve VII [1,6,9].

Tardive dyskinesia is a condition characterized by involuntary, choreiform movements of the face and tongue associated with chronic neuroleptic medication use. Common movements include chewing, sucking, mouthing, licking, “fly-catching movements,” puckering, and smacking (buccal-lingual-masticatory syndrome). Choreiform movements of the trunk and extremities can also occur along with dystonic movements of the neck and trunk.

Athetosis is characterized by involuntary, slow, writhing, and repetitious movements. They are slower than choreiform movements and less sustained than dystonia. Athetosis may be seen alone or in combination with other movement disorders and itself leads to bizarre but characteristic postures. Any part of the body can be affected, but it is usually the face and distal upper extremities that are involved. Chorea is manifested as nonstereotyped, unpredictable, and jerky movements that interfere with purposeful motion. The movements are rapid, erratic, and complex and can be seen in any or all body parts but usually involve the oral structures, causing abnormal speech and respiratory patterns. Hemiballismus is an uncommon disorder consisting of extremely violent flinging of the arms and legs on one side of the body.

Myoclonus is one of the most common involuntary movement disorders of central nervous system origin. It is characterized by sudden, jerky, irregular contractions of a muscle or groups of muscles. It can be subdivided into stimulus-sensitive myoclonus (reflex myoclonus), appearing with volitional movement, muscle stretch, or superficial stimuli such as touch, and non-stimulus-sensitive myoclonus, which occurs at rest (spontaneous myoclonus). Myoclonic movements can be either irregular or periodic [1,6].

Physical Examination

A complete physical examination is key to ruling out treatable causes of the presenting movement disorder, such as infectious (encephalitis), medication side effect (tardive dyskinesia), genetic (Tourette syndrome), or endocrinologic (tremor-associated thyrotoxicosis).

A good neurologic examination of patients thought to have a movement disorder helps identify an underlying causative condition, such as stroke (e.g., cerebrovascular-based Parkinson disease, hemiballismus, or ataxia), tumor, brain trauma, or even peripheral nerve injury-associated focal dystonias. Other aspects of physical examination focus on characterization of the type of abnormal movements by detailing of their body distribution (limb, trunk, head, face, or widespread), their quality (tremor, writhing, explosive, rigidity), their frequency (rapid and repetitive or slow and sustained), and their general quantity or lack thereof (hyperactive or hypoactive).

For instance, essential tremor (senile tremor) is usually rapid and fine and occurs when the patient is asked to hold the arms outstretched, whereas parkinsonian tremor

decreases with voluntary movement. Intention (cerebellar) tremor is slow and broad, occurring at the end of a purposeful motion, as when the patient executes a finger to nose task. In addition to tests of cerebellar function, tests for upper motor neuron syndrome (hyperreflexia, spasticity, presence of Babinski sign) may assist the examiner in distinguishing movement disorders more commonly associated with stroke or brain injury.

Functional Limitations

Functional limitations depend on the severity of the movement disorder. Some tremors and tics may be more a cosmetic and psychological concern, whereas severe postural disturbance in Parkinson disease or stroke-induced ataxia can clearly impair ambulation or upper extremity control. In Parkinson disease, postural changes, such as stooping with the development of permanent kyphosis, can occur after years of disease. Many physical activities require additional effort to be performed. Manual dexterity is invariably impaired as Parkinson disease worsens, affecting many daily activities, such as dressing, cutting food, writing, and handling small objects such as coins [10]. Soft, monotone, hoarse voice quality and imprecise articulation, together with restricted facial expression (masked facies), contribute to limitations in communication in a large majority of individuals with Parkinson disease, with 30% reporting it the most debilitating deficit. These functional losses negatively affect quality of life, leading to declining efficiency at work and, in many cases, abandonment of many leisure activities. Depression and social isolation are commonly seen in patients with Parkinson disease.

In cervical dystonia (torticollis), social stigmatization is a major concern, as are functional impairments, which can include driving, reading, and activities that involve looking down and using the hands. In another focal dystonia, writer's or occupational cramp, the symptoms are manifested in a certain posture or position; for instance, a patient may be able to write at a blackboard but not seated at a desk. With lingual involvement in oromandibular dystonia, the tongue has abnormal movements during speaking or deglutition. The result of such dystonias is impairment of speech and eating [9]. In Huntington chorea, along with the choreiform movement, progressive dementia and emotional and behavioral abnormalities are seen. As the disease progresses, the presentation becomes less choreiform and more parkinsonian and dystonic (i.e., restricted motions, immobility, and unsteadiness of gait). Intellectual impairment and psychosis invariably occur and progress rapidly to become the most disabling features [6].

Diagnostic Studies

In most cases of movement disorders, such as Parkinson disease, tardive dyskinesia, essential tremor, and dystonia, the diagnosis is made on the grounds of clinical examination and history; no one specific test is pathognomonic for the disease [5–7]. Positron emission tomography and single-photon emission computed tomography scans are able to identify altered brain dopaminergic activity; however, their superiority over clinical diagnosis is unclear at this time [6]. Evaluation for potential causes of the other

movement disorders, such as stroke, traumatic brain injury, normal-pressure hydrocephalus, tumor, infection, and metabolic or endocrinologic disease, should be performed with appropriate tests, including head and spinal magnetic resonance imaging and computed tomography, cerebrospinal fluid analysis, and blood serum analysis. Electrodiagnostic tests (electromyography and nerve conduction studies) may be useful in some cases, such as focal dystonias, to rule out coexisting or causative peripheral nerve entrapment. Electroencephalography is often helpful in distinguishing focal seizures from myoclonus or other repetitive movement presentations [11]. More tests may be necessary to confirm or to exclude other diagnoses, such as human immunodeficiency virus–related diseases, central nervous system infection, toxic exposures, Wilson disease, and psychiatric illnesses. Videofluoroscopy should be ordered to more accurately characterize swallow dysfunction and to assist with treatment planning when the clinical examination findings or symptoms suggest dysphagia.

Differential Diagnosis

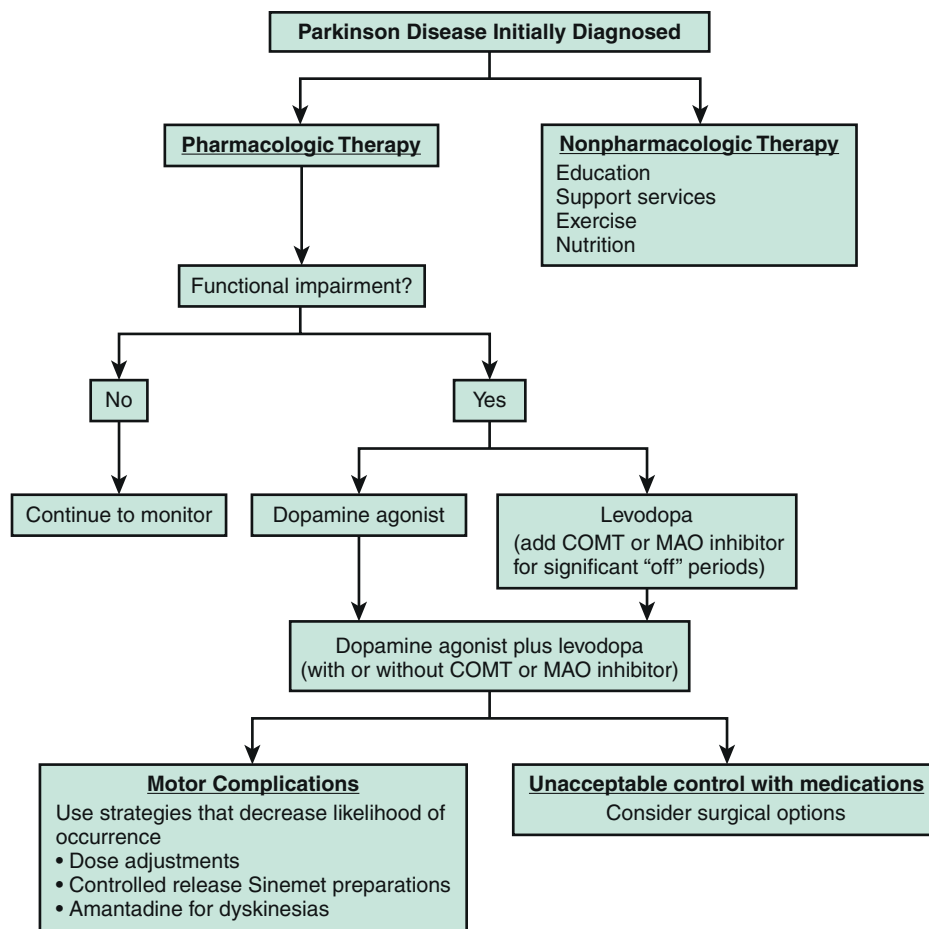

Seizures
Psychiatric illness
Spasticity, spasms

Treatment

Initial

Treatment is highly dependent on which specific category of movement disorder is present. Typically, pharmacologic treatment is initiated when the symptoms become severe enough to cause discomfort or disability (Fig. 133.1).

Antiparkinson medications replace dopamine (levodopa), act as a postsynaptic (dopamine) agonist, increase the availability of levodopa or dopamine by preventing their metabolism (catechol-*O*-methyltransferase, monamine oxidase B inhibitors), or reestablish the dopamine-acetylcholine balance in the striatum (anticholinergics). Levodopa in combination with carbidopa (Sinemet) continues to be the most effective medication for treatment of Parkinson disease symptoms, but it is usually not the first medication given to those newly diagnosed, particularly in younger patients. The dopamine agonists bromocriptine (Parlodel), ropinirole (Requip), and pramipexole (Mirapex) or the recently approved rotigotine (Neupro) transdermal patch can be used as monotherapies in mild, early Parkinson disease, as can the monamine oxidase B inhibitors selegiline (Eldepryl, Zelapar) and rasagiline (Azilect). Loss of levodopa efficacy usually develops within 3 to 5 years after the medication is begun, so an effort is made to manage early Parkinson disease with other medications. A guiding principle is to start levodopa treatment in patients with symptoms that interfere with the performance of daily life functions despite other treatment. Its long-term use is associated with the development of motor fluctuations and dyskinesias. Over time, as the disease worsens, the patient's frequency of levodopa dosing and the total dose needed will increase, along with the need for other supplemental medications, such as the dopamine agonists and monamine oxidase B inhibitors, to help counter

Note: MAO inhibitors can be used as initial monotherapy, but only modestly effective.
Anticholinergics can be tried with younger patients for prominent tremor.

FIGURE 133.1 Algorithm for medication management of Parkinson disease. COMT, catechol-O-methyltransferase; MAO, monamine oxidase.

worsening motor fluctuations [12]. For patients with significant “off time,” the catechol-*O*-methyltransferase inhibitors entacapone (Comtan) and tolcapone (Tasmar) are used in combination with levodopa/carbidopa, slowing its breakdown and augmenting its effectiveness. Because hepatic disease has been reported with tolcapone use, liver function test monitoring is required.

Anticholinergic drugs such as trihexyphenidyl (Artane) and benztropine (Cogentin) are used less widely today because of their side effect profile and limited efficacy for rigidity and bradykinesia. They are useful primarily for younger patients with tremor as their primary symptom [3,5,6,12,13].

A continuous pump-based infusion of levodopa/carbidopa directly into the small intestines through an implanted catheter has shown efficacy in Parkinson disease patients suffering motor fluctuations and is presently undergoing clinical trials the United States [14].

Propranolol is the most useful medication in treating essential tremor (the most common symptomatic tremor), task-specific tremor, and action tremor. Other beta blockers have fewer side effects but are less effective. The anti-convulsant primidone and the benzodiazepine clonazepam are also effective antitremor drugs. Gabapentin and botulinum toxin injections may be of some benefit in tremor

management [1,2,6]. Tics can be managed with neuroleptics; pimozide and haloperidol are generally effective, but sedation limits their use. Newer atypical neuroleptics may have fewer side effects, including risperidone, quetiapine, olanzapine, and clozapine. Other medications shown to be of some benefit include clonazepam, clonidine, calcium channel blockers, and antidepressant agents [1,6]. Anticholinergic medications, such as trihexyphenidyl and benztropine, are the most effective oral agents for both generalized and focal dystonias in younger patients. Baclofen (either orally or by intrathecal pump), carbamazepine, and the benzodiazepines, such as diazepam and clonazepam, are sometimes helpful. Dopamine-blocking or dopamine-depleting agents may be used to treat some patients with dystonia. Focal dystonias are now commonly treated with botulinum toxin injections [6,9] (see the section on procedures).

Replacement of typical antipsychotic drugs with the atypical neuroleptics, such as clozapine and risperidone, is useful to control psychosis in patients with tardive dyskinesia without worsening of symptoms. Other drugs, such as benzodiazepines, adrenergic antagonists, and dopamine agonists, may also be beneficial for suppression of the movements. The most important step in the treatment of tardive dyskinesia is prevention by limiting the use of neuroleptic

medications [15]. The response to drug therapy has been poor in patients with ataxia; many agents have been touted as useful (propranolol, isoniazid, carbamazepine, clonazepam, tryptophan, buspirone, thyroid-stimulating hormone), but none has demonstrated efficacy [16]. A number of drugs have been used to treat myoclonus and can be effective in some situations. These include diazepam, clonazepam, valproate, and levetiracetam (Keppra) as well as botulinum toxin injections [11].

Rehabilitation

In general, the patient with Parkinson disease needs to be counseled to maintain a reasonable level of activity at all costs as physical exertion becomes more difficult and the risk of deconditioning increases. Exercises focus on proper body alignment (upright posture) and postural reflexes (response to dynamic balance challenges) as well as on limb range of motion and strengthening of proximal musculature to assist in stair climbing and coming to a stand. Exercises are also aimed at the restoration of diminished reciprocal limb motions and an increase in step length and can include treadmill training. A number of randomized studies in Parkinson disease patients have demonstrated benefits such as improved walking speed and endurance, step length, and balance with several forms of exercise [17,18].

The tendency to freeze can be reduced with visual targets, such as markers on the floor, counting, or marching rhythmically. The difficulty in rising from sitting surfaces can be addressed with elevated sitting surfaces (chair, toilet) and strategically placed grab rails or bars (bed, bathtub). Although wheeled walkers are useful in assisting ambulation, particularly by preventing backward instability, patients with significant postural deficits may prefer more stable devices, such as a supermarket shopping cart or walking behind a wheelchair. Adaptive equipment is provided when deficits in upper extremity control limit efficient and safe function [19,20]. Speech therapy is useful in patients with Parkinson disease to improve articulation and loudness as well as to diagnose and to manage dysphagia [13,21].

In tremor, measures to reduce or to alleviate anxiety (e.g., biofeedback, relaxation exercises) are useful, as are strategies to control oscillation excursion with weights or other mechanical compensations [20]. Lifestyle changes may include restriction of caffeine intake or other stimulants that may temporarily augment symptoms. In addition, alcohol consumption may lead to transient improvement for many with essential tremor [2,6].

Stretching exercises may be important for maintenance or recovery of range of motion for affected joints in a dystonic limb. Certain types of occupation-based focal limb dystonias (e.g., writer's or musician's cramp) may be treated with muscle reeducation techniques, including biofeedback. A regular program of stretching exercises may assist affected individuals in regaining full range of motion after a botulinum toxin injection has weakened a dystonic muscle. Some patients use so-called sensory tricks to temporarily relieve their symptoms. These commonly involve touching or stroking a particular spot on the skin. In addition, in some patients, certain types of braces may provide the same stimulation and be equally effective [14,20].

Ataxic patients may benefit from rehabilitation to help them learn compensatory techniques for performance of basic self-care and occupational activities and to assess the benefits of weighted bracelets or similar devices to damp the oscillations. Gait training and education in the use of assistive devices for walking can prevent falls and enhance mobility in the ataxic individual. In disorders involving athetosis, ballismus, or Huntington disease, careful weighting of the extremities can help at times. Rehabilitation techniques involving improvement of coactivation and trunk stability, rhythmic stabilization, and traditional relaxation techniques including biofeedback have been mentioned as reasonable strategies. Some have suggested value in oral desensitization when hyperreactivity to sensory stimuli exists for reducing excessive facial movements in tardive dyskinesia, but other rehabilitation strategies are not of proven utility [20].

Procedures

Botulinum toxin injections are beneficial in numerous hyperkinetic movement disorders, including focal dystonias, tremor, and myoclonus. Trigger point injections may provide relief in painful muscles associated with focal dystonias (e.g., cervical torticollis).

The muscles selected for botulinum toxin injection are based on understanding of the primary clinical patterns of spasticity or dystonia. Direct injection by palpation technique may be appropriate for superficial muscles; electromyography or electrical stimulation guidance is commonly used to identify deeper muscles. Each muscle is injected in one or more sites, the number being a function of the size of the muscle. Dosage is variable but typically does not exceed 400 units total body dose for a 3-month period. Botulinum toxin A is reconstituted in the vial with preservative-free normal saline, at varying dilutions depending on the muscle size. For example, an average size muscle, such as flexor carpi radialis, could receive a concentration of 10 units per 0.1 mL.

The skin is cleaned with an alcohol or iodine swab and allowed to dry. When electromyography or electrical stimulation guidance is used, a specialized needle with an exposed tip connected by wire to the recording or stimulating device is needed. Needles are typically 37 mm in length and 27-gauge; larger or smaller needles are often needed, depending on muscle size and depth. In adults, pre-anesthetization of the skin is usually unnecessary; in children, local anesthetic creams are helpful. When botulinum toxin is injected, aspiration of the syringe to prevent injection into a blood vessel is standard technique. Before the injection, informed consent is obtained.

For Parkinson patients, cell transplants and gene therapies continue as experimental procedures still under investigation [13].

Surgery

Deep brain stimulation (subthalamic nuclei, globus pallidus) has been proven efficacious and has largely replaced neuroablative lesion procedures, such as thalamotomy and pallidotomy, for Parkinson disease [1,6,22]. Both deep brain stimulation and ablative surgery are also used for severe cases of other movement disorders, such as tremor or

dystonia. In addition, peripheral destructive procedures, such as myectomy, rhizotomy, and peripheral nerve denervation, are occasionally performed on individuals with dystonic limbs who have proved refractory to more conventional management.

Potential Disease Complications

Many of the movement disorders, particularly Parkinson disease, are progressive and can result in muscle weakness and immobility, severe limb contractures, aspiration of food and respiratory compromise, social isolation and depression, and intellectual impairment and dementia.

Potential Treatment Complications

Antiparkinson medications may have numerous side effects, including nausea and other gastrointestinal symptoms, drowsiness, confusion, hallucinations, psychosis, and motor dyskinesia. Similar adverse medication effects are described with other agents used to suppress unwanted movements. Botulinum toxin is generally well tolerated but can cause transient unwanted weakness in target or adjacent muscles, including dysphagia. Risks associated with surgical approaches to central nervous system structures are considerable and need to be properly weighed before these options are selected [1,6,22].

Definition

Multiple sclerosis (MS) can be defined as an inflammatory disorder that results in damage, primarily to myelin sheaths and oligodendrocytes and less so to axons and nerve cells, in the central nervous system [1,2].

The prevalence of MS has been estimated at 300,000 to 400,000 in the United States and 2 million worldwide [3]. The disease usually becomes clinically apparent between the ages of 20 and 40 years, with a peak incidence at 24 to 30 years and onset as late as the seventh decade [3]. The disease appears twice as likely to develop in women as in men, and whites are more frequently diagnosed than are other races [3]. Although African Americans may experience greater MS-related disability than white individuals do, the disease progresses similarly for both races [3,4].

There are four common clinical courses in MS:

- Relapsing-remitting MS: Patients experience episodes of acute worsening of neurologic function followed by periods of remission. Patients may exhibit residual deficits after the episode of exacerbation. Most patients start with this course.
- Secondary progressive MS: Patients initially experience a relapsing-remitting course followed by progression of the disease with or without additional episodes

of exacerbation and improvement. Most patients eventually transition to this disease course.

- Primary progressive MS: Patients experience a relentless progression of symptoms from the onset [5,6].
- Progressive relapsing MS: Patients experience a baseline progressive course with episodes of acute relapses followed by a return to the baseline progressive course.

MS can be diagnosed if there is evidence of two attacks disseminated in time and space with clinical, laboratory, or imaging evidence of at least two lesions in the brain or spinal cord [1–3,7]. Evidence may be obtained from clinical findings, magnetic resonance imaging, cerebrospinal fluid analysis, or visual evoked potentials [6,7]. Other diseases that could explain the symptoms must be excluded (see differential diagnosis) [8,9]. The most recent guidelines and revisions do not recommend the use of “clinically definite MS” or “probable MS”; the outcome of a diagnostic evaluation is MS, “possible MS,” or “not MS” (Table 134.1) [2,6,7].

Symptoms

Symptoms of MS may involve multiple systems [10,11] (Table 134.2). Motor symptoms typically include weakness and spasticity [11]. Up to 85% of patients with MS may experience spasticity, and as many as a third may be affected by spasticity that is severe enough to diminish their quality of life [12]. Patients with MS may report paroxysmal spasms or nocturnal spasms.

MS may be the cause of decreased or even absent sensation in various body parts, including sensory levels that most often affect the trunk. Paresthesia (uncomfortable abnormal sensation that may be described by the patient as pain, pins and needles, or tingling) can occur in up to 50% of patients with MS and most commonly is neuropathic. Lhermitte sign is an electric shock-like sensation that radiates down the spine to the legs when the neck is flexed [10]. It may occur in up to 40% of patients with MS [7]. Multiple pain syndromes may occur in patients with MS [11,13] (Table 134.3). Visual symptoms may include optic neuritis that results from inflammation of the optic nerves and typically is manifested as retro-orbital pain or painful eye movements [14]. Visual deficits can range from mild distortions to complete visual loss [14]. Scotoma may be present as an area in the visual field with absent or impaired vision and dyschromatopsia as imperfect color vision [14]. Ocular motor deficits usually include internuclear ophthalmoplegia and nystagmus and are manifested as diplopia, blurry vision, and reading fatigue [14].

Table 134.1 The 2010 McDonald Criteria for Diagnosis of Multiple Sclerosis

Clinical Presentation	Additional Data Needed for MS Diagnosis
<p>≥2 attacks*; objective clinical evidence of ≥2 lesions or objective clinical evidence of 1 lesion with reasonable historical evidence of a prior attack†</p> <p>≥2 attacks*; objective clinical evidence of 1 lesion</p>	<p>None‡</p>
<p>1 attack*; objective clinical evidence of ≥2 lesions</p>	<p>Dissemination in space, demonstrated by:</p> <ul style="list-style-type: none"> ≥1 T2 lesion in at least 2 of 4 MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord)§; or Await a further clinical attack* implicating a different CNS site <p>Dissemination in time, demonstrated by:</p> <ul style="list-style-type: none"> Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time; or A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan; or Await a second clinical attack*
<p>1 attack*; objective clinical evidence of 1 lesion (clinically isolated syndrome)</p>	<p>Dissemination in space and time, demonstrated by:</p> <p>For DIS:</p> <ul style="list-style-type: none"> ≥1 T2 lesion in at least 2 of 4 MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord)§; or Await a second clinical attack* implicating a different CNS site; and <p>For DIT:</p> <ul style="list-style-type: none"> Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time; or A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan; or Await a second clinical attack*
<p>Insidious neurological progression suggestive of MS (PPMS)</p>	<p>1 year of disease progression (retrospectively or prospectively determined) plus 2 of 3 of the following criteria§:</p> <ol style="list-style-type: none"> 1. Evidence for DIS in the brain based on ≥1 T2 lesions in the MS-characteristic (periventricular, juxtacortical, or infratentorial) regions 2. Evidence for DIS in the spinal cord based on ≥2 T2 lesions in the cord 3. Positive CSF (isoelectric focusing evidence of oligoclonal bands and/or elevated IgG index)

If the criteria are fulfilled and there is no better explanation for the clinical presentation, the diagnosis is “MS”; if suspicious, but the criteria are not completely met, the diagnosis is “possible MS”; if another diagnosis arises during the evaluation that better explains the clinical presentation, then the diagnosis is “not MS.”

MS, multiple sclerosis; CNS, central nervous system; MRI, magnetic resonance imaging; DIS, dissemination in space; DIT, dissemination in time; PPMS, primary progressive multiple sclerosis; CSF, cerebrospinal fluid; IgG, immunoglobulin G.

*An attack (relapse; exacerbation) is defined as patient-reported or objectively observed events typical of an acute inflammatory demyelinating event in the CNS, current or historical, with duration of at least 24 hours, in the absence of fever or infection. It should be documented by contemporaneous neurological examination, but some historical events with symptoms and evolution characteristic for MS, but for which no objective neurological findings are documented, can provide reasonable evidence of a prior demyelinating event. Reports of paroxysmal symptoms (historical or current) should, however, consist of multiple episodes occurring over not less than 24 hours. Before a definite diagnosis of MS can be made, at least 1 attack must be corroborated by findings on neurological examination, visual evoked potential response in patients reporting prior visual disturbance, or MRI consistent with demyelination in the area of the CNS implicated in the historical report of neurological symptoms.

†Clinical diagnosis based on objective clinical findings for 2 attacks is most secure. Reasonable historical evidence for 1 past attack, in the absence of documented objective neurological findings, can include historical events with symptoms and evolution characteristics for a prior inflammatory demyelinating event; at least 1 attack, however, must be supported by objective findings.

‡No additional tests are required. However, it is desirable that any diagnosis of MS be made with access to imaging based on these criteria. If imaging or other tests (for instance, CSF) are undertaken and are negative, extreme caution needs to be taken before making a diagnosis of MS, and alternative diagnoses must be considered. There must be no better explanation for the clinical presentation, and objective evidence must be present to support a diagnosis of MS.

§Gadolinium-enhancing lesions are not required; symptomatic lesions are excluded from consideration in subjects with brainstem or spinal cord syndromes. From Polman CH, Reingold SC, Banwell B, et al. Diagnostic criteria for multiple sclerosis: 2010 revisions to the McDonald criteria. *Ann Neurol* 2011;69:292-302.

Cerebellar symptoms may include tremor, which can range from mildly annoying to disabling, be gross or fine, and occur at rest or with purposeful actions. Various parts of the body may be involved, including the head, the upper or lower limbs, and the trunk.

Constipation and bowel incontinence may occur in up to 73% of patients with MS [15]. More than 70% of patients with MS may suffer from bladder dysfunction [15]. MS lesions in the spinal cord can result in a small spastic bladder due to detrusor overactivity. This usually is manifested as urinary urgency, frequency, voiding of small amounts of urine, and eventually incontinence [15]. Bladder

underactivity can result in retention and overflow incontinence. Bladder dysfunction is often associated with urinary tract infections that can worsen MS symptoms. Sexual dysfunction commonly includes erectile and ejaculatory dysfunction in men; vaginal dryness in women; and increased time to arousal, decreased genital sensation, and decreased libido in men and women [15]. Factors contributing to sexual dysfunction include disease progression, antidepressants, fatigue, and depression [15].

Involvement of cranial nerves VII, IX, X, and XII may result in dysphagia or swallowing difficulties. These are manifested as coughing, frequent throat clearing, complaints of

Table 134.2 Common Symptoms in Multiple Sclerosis

Bladder symptoms	Urgency, frequency, hesitancy, retention, incontinence
Bowel symptoms	Constipation, urgency, incontinence
Cerebellar symptoms	Incoordination, imbalance, tremor
Cognition	Concentration, memory, executive dysfunction
Fatigue	Lassitude, reduced endurance
Mood disorders	Depression, anxiety, emotional lability
Motor	Weakness, spasticity
Sensory symptoms	Loss of sensation, positive sensations
Sexual dysfunction	Decreased libido, erectile dysfunction
Vision	Visual loss and double vision

From Goldman MD, Cohen JA, Fox RJ, Bethoux FA. Multiple sclerosis: treating symptoms, and other general medical issues. *Cleve Clin J Med* 2006;73:178.

food “sticking” in the throat, weight loss, weak voice, choking, or even aspiration pneumonia [16].

Fatigue has been reported to occur in more than 90% of MS patients and is regarded as the most disabling symptom in as many as 60% of these patients [15,17]. MS-related fatigue has been described as an overwhelming feeling of tiredness, lack of energy, or exhaustion exceeding the expected [15,17].

As many as 50% of patients with MS may have cognitive deficits that are manifested as problems with memory, planning, concentration, judgment, problem solving, and processing speed [18–21]. MS patients frequently report heat intolerance with an exacerbation of symptoms in warm or humid environments [22].

Physical Examination

Inflammation of the optic nerve may result in optic or retrobulbar neuritis manifesting as acute vision loss. Even after treatment, vision deficits may persist in the form of poor vision, especially in dim light, or blind spots in the visual field known as scotomas. Demyelination in the medial longitudinal fasciculus may result in varying degrees of horizontal nystagmus; involvement of the third cranial nerve may be manifested as a persistently enlarged pupil. Double vision

may be attributable to weakened strength and coordination in the eye muscles. Cataracts may develop at an earlier age in the MS population because of the use of steroids. Visual problems may worsen with stress, increased temperature, and infection [14].

Speech dysfunction may include dysarthria with diminished fluency, slurring, decreased speed, and eventually incomprehensibility.

Sensory testing may reveal deficits in pinprick, temperature, proprioception, or vibration. A sensory level may be evident.

Manual muscle testing can show varying degrees of muscle weakness. The patient may exhibit poor control of a limb or insufficient clearance of the foot during gait. Spastic gait may be another motor finding. Cerebellar involvement may be manifested as dysmetria with past pointing on finger to nose testing and uncoordinated heel to shin movements. The Ashworth Scale (or Modified Ashworth Scale) [23] is commonly used to measure the amount of spasticity, and the 88-item Multiple Sclerosis Spasticity Scale is a reliable and valid measure of the impact of spasticity in patients with MS [24].

Early in the course, deep tendon reflexes tend to be hyperactive. Decreased or absent reflexes can represent segmental levels of deficit. Corticospinal tract involvement may be evident with an asymmetric plantar response or loss of the abdominal reflex. Deep tendon reflexes can also be asymmetric; testing them in more than one position can determine the consistency of the findings.

Cognitive testing may reveal multiple deficits, including in memory, problem solving, judgment, and concentration.

Functional Limitations

The combinations of deficits in MS lead to difficulties with activities of daily living and mobility. Weakness, incoordination, spasticity, or sensory deficits may each or in combination contribute to falls. In addition to possible injuries, these falls may lead to decreased mobility because of fear of repeated falls. Decreased mobility itself leads to further weakness, decreased endurance, and less independence. Weakness or spasticity can also lead to difficulties with feeding and self-care, resulting in the need for personal care

Table 134.3 Multiple Sclerosis Pain Syndromes and Their Treatment

Pain Syndrome	Acute or Chronic	Clinical Example	Treatment Approaches
Neuralgia	Both	Trigeminal neuralgia	Gabapentin, 100-900 mg three or four times daily Carbamazepine, 200-400 mg three times daily (extended-release form also available) Dilantin, 300-600 mg daily Oxcarbazepine, 150-900 mg daily Amitriptyline, 10-100 mg daily at bedtime Other tricyclic antidepressants Baclofen (oral or intrathecal) as adjuvant therapy Intravenous corticosteroids directed at underlying inflammation
Meningeal irritation	Acute	Optic neuritis	Same as for neuralgia
Sensory pain	Both	Paresthesias	Rehabilitation (physical and occupational therapy)
Skeletal muscle pain	Chronic	With spasticity or limited mobility	Assistive devices Nonsteroidal anti-inflammatory drugs

From Goldman MD, Cohen JA, Fox RJ, Bethoux FA. Multiple sclerosis: treating symptoms, and other general medical issues. *Cleve Clin J Med* 2006; 73:182.

attendants. The Multiple Sclerosis Functional Composite is a clinical measure developed by a task force of the National Multiple Sclerosis Society [25,26] and is mostly used in clinical trials. It measures ambulation, arm and hand function, and cognition and has been found to have greater reliability, sensitivity, and validity than the Kurtzke Expanded Disability Status Scale [3].

Bowel and bladder dysfunction can contribute to many embarrassing moments in the community, causing patients with MS to fear leaving home or to become distracted by seeking out the locations of bathrooms in areas they plan to visit. Many resort to wearing diapers or catheters. Fear of bladder incontinence may also lead a patient to decrease fluid intake, resulting in dehydration.

Depression, insomnia, and fatigue can all contribute to activity intolerance.

Visual deficits may limit activities such as driving and reading, thus limiting participation in work and recreation.

Diagnostic Studies

Magnetic resonance imaging is the most important test in the diagnosis and management of MS [27]. The use of gadolinium allows enhancement of active inflammatory lesions that represent areas with blood-brain barrier breakdown. These hyperintense lesions on T2-weighted images are more specific for MS if they are located in the cerebral white matter, especially the corpus callosum, periventricular area, and brainstem [6].

Cerebrospinal fluid studies, visual evoked potentials, and brainstem auditory evoked potentials can assist in the diagnosis of MS when magnetic resonance imaging findings but not clinical findings support a diagnosis of MS [6,22].

Differential Diagnosis

Acute disseminated encephalomyelitis
Cerebrovascular disease
Primary cerebral vasculitis
Systemic lupus erythematosus
Polyarteritis nodosa
Familial cavernous hemangiomas
Eales disease with neurologic involvement
Sjögren syndrome
Inflammatory central nervous system disease
Migratory sensory neuritis
Behçet disease
Lyme disease
Chronic fatigue syndrome
Neurobrucellosis
Neurosarcoidosis
Metastatic and remote effects of cancer
Multiple metastases
Paraneoplastic syndromes
Vitamin B₁₂ deficiency
Myasthenia gravis
Human T-lymphotropic virus 1–associated myelopathy
Acquired immunodeficiency syndrome myelopathy
Other human immunodeficiency virus syndromes
Adult-onset leukodystrophy
Herpes zoster myelitis
Arachnoiditis

Treatment

Initial

Treatment of patients with MS requires a multidisciplinary approach that should involve careful identification of the symptoms with consideration given to the consequences of these symptoms. Symptoms then need to be prioritized and a treatment plan formulated with use, where appropriate, of nonpharmacologic interventions first [28–33].

Education of the patient and family should be included in any initial treatment plan involving patients with MS. This provides information about a balanced diet [34], including adequate fluid intake, weight control, and appropriate exercise [35]. The patient is encouraged to continue working and participating in recreational activities for as long as possible. Modifications may be necessary to allow these activities to continue. The health care providers, the family, and the patient should closely monitor emotional stability, especially mood, because such conditions as depression can contribute to disability. Disabled parking placards can make the task of driving and parking more convenient for the disabled patient with MS.

High-dose methylprednisolone for 3 to 5 days has been established as effective treatment of acute relapses [36,37]. This can be given in a home or hospital setting with similar efficacy [38]. The medications approved by the U.S. Food and Drug Administration (FDA) that are available as first-line treatment to decrease the relapse rate in relapsing-remitting MS include interferon beta-1a (Avonex, Rebif), interferon beta-1b (Betaseron, Extavia), glatiramer acetate (Copaxone), mitoxantrone (Novantrone), natalizumab (Tysabri), and fingolimod (Gilenya) [39]. Fingolimod offers the advantage of oral administration and may be the most effective in decreasing relapse frequency in relapsing-remitting MS [40].

Spasticity management can be complex (see Chapter 153). Some patients use their spasticity to assist with transfers or gait; therefore, spasticity should be treated only if it interferes with mobility or activities of daily living. The first step is seeking and treatment of noxious stimuli, such as pain or infection, especially urinary tract infections, because such stimuli can exacerbate spasticity [41]. Treatment options include physical therapy (see the section on rehabilitation), oral or intrathecal medications, and nerve or muscle blocks [41].

Oral baclofen is the usual first-line treatment, starting with 5 mg two or three times per day and titrating up to the FDA-recommended maximum of 80 mg/day in divided doses. Patients with severe spasticity may require and have been shown to tolerate higher doses (up to 160 mg/day) [42]. Tizanidine, an α -adrenergic receptor antagonist, has been shown to be effective in reducing muscle tone in patients with MS [43]. Dosing should be started at 2 mg and slowly increased to the effective dose of 24 to 36 mg/day in three divided doses [41]. Side effects can include sedation, dry mouth, and weakness. Tizanidine may cause less weakness but more severe dry mouth compared with baclofen [44]. The GABAergic drugs gabapentin (Neurontin) and pregabalin (Lyrica) have been shown to have antispasticity properties [41] and can be used as monotherapy or in addition to baclofen or tizanidine. Sedation is the most common side effect. Benzodiazepines, such as diazepam (Valium) at

5 to 7.5 mg and clonazepam (Klonopin) at 0.5 to 1.5 mg, can be sedating and so are best used at bedtime for nocturnal spasms. They have addiction potential.

A third-line oral antispasticity option is dantrolene sodium, a direct-acting muscle relaxant [41]. It may be best for the nonambulatory patient with MS with severe spasticity who may be unaffected by the resultant weakness.

Back spasms in patients with MS may respond to cyclobenzaprine (Flexeril). Intractable spasticity may be managed with muscle or nerve blocks or intrathecal administration of baclofen (see the section on procedures).

Bladder dysfunction should be initially assessed with a urinalysis and urine culture to determine if a urinary tract infection is present. Appropriate antibiotics should be used for a urinary tract infection. If there is no infection or improvement after antibiotic treatment, a postvoid residual urine volume by ultrasound can help determine failure-to-empty (postvoid residual > 100 mL) or failure-to-store (postvoid residual < 100 mL) dysfunction [45]. A urodynamic study can help determine the presence (or absence) of detrusor hyperreflexia, detrusor-sphincter dyssynergia, or detrusor areflexia. Nonpharmacologic interventions for bladder dysfunction include timed voiding, minimizing the intake of bladder irritants such as caffeine, and regulation of fluid intake. Detrusor hyperactivity may respond to anticholinergic medications, such as the nonselective muscarinics oxybutynin (Ditropan), tolterodine (Detrol), trospium (Sanctura), and fesoterodine (Toviaz). Alternatively, the selective M₂ and M₃ antimuscarinics darifenacin (Enblex) and solifenacin (VESIcare) may be used [15]. The main side effects of the anticholinergics are dry mouth and constipation. Transdermal oxybutynin may offer even fewer side effects. Botulinum toxin type A injections into the detrusor muscle have shown efficacy in reducing symptoms in patients with detrusor hyperreflexia [46]. Detrusor underactivity is best managed with clean intermittent catheterization [45]. Cholinergic agents such as bethanechol (Urecholine) and tamsulosin may also reduce bladder urine volume [15]. Detrusor-sphincter dyssynergia may respond to a combination of clean intermittent catheterization and anticholinergic drugs [15]. Patients with MS and bladder dysfunction may eventually need continuous drainage by a suprapubic catheter. Urology consultation may be necessary for further workup and treatment in complicated cases that are not responding well to medications or for those patients requiring suprapubic catheterization. Surgical procedures may be necessary (see the section on surgery).

Sexual dysfunction in men with MS may be treated with oral medications such as sildenafil, vardenafil, and tadalafil if the problem is erectile dysfunction [47]. Intraurethral or penile injections of papaverine or alprostadil, mechanical vibrators, and vacuum devices can enhance arousal and orgasm [11,18]. Treatment of sexual dysfunction should include counseling and education [18,48]. Sildenafil may help improve lubrication in women with MS and sexual dysfunction [49].

Bowel dysfunction manifesting as constipation is best managed by establishment of a bowel program. This consists of adequate fluid intake, incorporation of fiber, adherence to a bowel elimination schedule, biofeedback, maintenance of physical activity, and judicious use of medications [15,18]. Fluid intake should be at least 8 cups each day. Fiber can

Table 134.4 Nonpharmacologic Interventions for Management of Fatigue in Patients with Multiple Sclerosis

Intervention	Method
Treat underlying factors that exacerbate fatigue	Correction of sleep disturbances Treatment of depression Reversal of thyroid abnormalities Management of medication adverse effects
Improve physical fitness Improve mobility	Aerobic exercise Physical and occupational therapy Instruction in proper use of mobility aids and techniques
Teach energy conservation	Timed rest periods Work simplification techniques
Teach cooling techniques	Avoidance of heat Use of cooling vests or other garments

From Crayton HJ, Rossman HS. Managing the symptoms of multiple sclerosis: a multimodal approach. *Clin Ther* 2006;28:449.

be found in such foods as raw fruits and vegetables, whole grains, nuts, and seeds. Bowel elimination is most likely to occur shortly after a meal when the gastrocolic reflex results in an increase in the movement of intestinal contents; allow up to 30 minutes of uninterrupted time. Bulk formers, stool softeners, laxatives, rectal stimulants such as suppositories, or occasional use of enemas may be necessary. Diarrhea may be managed by bulk formers taken once per day without the extra fluid as in treatment of constipation. Medications such as loperamide, to slow bowel activity, may be necessary in patients with chronic diarrhea with fecal incontinence [18]. Workup should seek to eliminate other causes of diarrhea, such as *Clostridium difficile* infection or lactose intolerance.

Factors contributing to or mimicking fatigue should be ruled out or identified and addressed. Common factors are thyroid dysfunction, anemia, sleep disturbance, infections, and sedating medications [15,18]. Treatment should include nonpharmacologic [50] (Table 134.4) and, if necessary, pharmacologic interventions. First-line medications include amantadine [51,52] (Symmetrel), started at 100 mg in the morning and early afternoon, and modafinil [51] (Provigil), 100 to 400 mg in the morning. Pemoline (Cylert) and methylphenidate (Ritalin) are third-line medications [15]. Aspirin has been shown to improve fatigue in patients with MS [52].

The multiple pain syndromes in patients with MS are amenable to nonpharmacologic and pharmacologic interventions [11,53,54] (see Table 134.3).

Cognitive impairment can be detected during daily interactions with family, colleagues, and friends or during interactions with speech-language pathologists, physical therapists, and occupational therapists. Formal neuropsychological testing can determine the presence and severity of even subtle cognitive impairments [19]. Speech-language pathologists can teach compensatory techniques, such as repetition and maintaining a memory book. Donepezil was not shown

to improve MS-related cognitive dysfunctions [55,56]. Identifying and treating depression with antidepressant medication and counseling can be helpful [32].

Acute visual deficits attributable to inflammation may improve more rapidly after high-dose intravenous administration of methylprednisolone. Prism lenses may help compensate for double vision. Regular patching should be avoided because this may prevent the brain from learning to compensate for double vision; patching can be limited to specific activities, such as watching television or reading.

Rehabilitation

Physical therapy interventions to decrease spasticity include range of motion exercises, stretching, positioning, aerobic exercise, and relaxation techniques [32].

The physical therapist may also improve mobility by training the patient to use various assistive devices to compensate for weakness and fatigue. The physical therapist may also use transcutaneous electrical nerve stimulation to assist with pain management. Physical therapists can teach aerobic exercises to prevent deconditioning, to improve endurance, and thus to delay or to minimize the effects of fatigue [35]. Weakness due to the “short circuiting” in demyelinated nerves, as can occur in MS, may be made worse if the patient exercises to the point of fatigue. Exercise programs should be individualized and updated as the patient’s condition changes [35]. Occupational therapists can help mitigate the effects of fatigue by teaching energy conservation and work simplification through the use of adaptive equipment and techniques.

Ataxia and tremor can be difficult symptoms to manage. Weighted utensils and weights on the distal limbs or assistive devices may lessen the effect of the tremor on a patient’s function [15]. Compensatory techniques taught by occupational therapy may improve activities of daily living. Medications for tremor may include beta blockers, buspirone, and clonazepam [15].

A speech-language pathologist can teach the patient techniques to improve speech intelligibility. Various oromotor exercises can help maintain oral muscle coordination [57]. Swallowing dysfunction should be evaluated with a videofluoroscopy study. The speech-language pathologist can also help determine the safest food texture for a patient with dysphagia [57]. Severe dysphagia may require placement of a gastrostomy tube for nutrition to be maintained [57].

A vocational rehabilitation counselor can play an important role in integrating the disabled MS patient back into the workforce.

Procedures

Muscle or nerve blocks should be reserved for patients with focal spasticity or generalized spasticity with a focal target, such as hip adductor spasticity that interferes with toileting. The most commonly used agents are botulinum toxin and phenol [41]. Intramuscular injection of botulinum toxin to specific muscles usually takes effect within a week, peaks in 2 to 3 weeks, and lasts 3 to 4 months. Side effects may include muscle weakness, atrophy, and diffusion to other

muscles. The maximum recommended dose of botulinum toxin is 400 units at a minimum interval of 3 months [41,58]. Resistance may occur from development of neutralizing antibodies. The neurolytic effect from phenol usually lasts 3 to 12 months, and the injection can be repeated. Side effects of the procedure include local soreness, edema, and fibrosis. Intrathecal administration of phenol has been used in selected patients whose spasticity was resistant to conventional treatment [41].

Surgery

Intrathecal administration of baclofen from a pump implanted in the abdomen is a reasonable option when oral antispasticity medications or muscle and nerve blocks are not tolerated or effective [59]. In rare cases, severe spasticity may need to be treated with stereotactic radiosurgery or deep brain stimulation [60] and refractory tremors with deep brain stimulation [61,62], thalamic stimulation, or thalamotomy [61–63]. Trigeminal neuralgia may be amenable to gamma knife radiosurgery [64]. Augmentation cystoplasty may be an option in patients with detrusor hyperreflexia that is refractory to conservative treatments [65].

Potential Disease Complications

MS has the potential to progress in such a way as to render the patient severely disabled both physically and cognitively. Dysphagia may lead to aspiration pneumonia that can cause death. Cervical myelopathy or severe demyelination in the brainstem may lead to respiratory failure. Complications related to the relative immobility include pneumonia, deep venous thrombosis, pulmonary embolism, and decubitus ulcers. Neurogenic bladder may contribute to urinary tract infections and even urosepsis. In a sample population of MS patients, half the deaths were due to pneumonia, pulmonary embolism, aspiration, urosepsis, and decubitus ulcers; respiratory complications accounted for most of the deaths [66]. The other deaths were similar to those in the general population. There may be a higher incidence of suicide in patients with MS [67]. If suicides are excluded, the life expectancy of patients with MS may be 6 to 7 years less than that of the general population [68].

Potential Treatment Complications

Corticosteroids may cause myriad adverse effects, including osteoporosis, immunosuppression, edema, cataracts, glaucoma, avascular necrosis, and myopathy. Interferon beta-1b and beta-1a may result in influenza-like symptoms and injection site reactions. Continued use of interferons may lead to the development of antibodies, rendering them less effective [69]. Baclofen and other antispasticity medications can lead to weakness, drowsiness, and dizziness [41]. If oral or intrathecal baclofen is abruptly withdrawn, hallucinations or seizures may occur [41]. Medications such as opiates for severe pain and benzodiazepines for tremor and spasticity have abuse potential. Dantrolene or tizanidine for spasticity may result in hepatitis, and liver enzymes should be monitored especially during the first 4 months [21]. Antidepressants may contribute to sexual dysfunction.

CHAPTER 135

Myopathies

Kristian Borg, MD, PhD

Erik Ensrud, MD

Synonym

Muscular dystrophies

ICD-9 Codes

- 359.0 Congenital hereditary muscular dystrophy
- 359.1 Hereditary progressive muscular dystrophy
- 359.2 Myotonic disorders
- 359.4 Toxic myopathy
- 359.5 Endocrine myopathy
- 359.6 Inflammatory myopathy in other diseases
- 359.8 Other myopathies
- 359.9 Myopathy, unspecified
- 710.3 Dermatomyositis
- 710.4 Polymyositis

ICD-10 Codes

- G71.0 Muscular dystrophy, congenital
- G71.19 Myotonic disorders
- G72.2 Myopathy due to other toxic agents
- E34.9 [G73.7] Endocrine myopathy
- G72.49 Inflammatory myopathy, not elsewhere classified
- G72.9 Myopathy, unspecified
- M33.90 Dermatomyositis, unspecified, organ involvement unspecified
- M33.20 Polymyositis, organ involvement unspecified

Definition

Myopathy is the common name for diseases derived from the muscle. Myopathies have different causes and different

courses, that is, they may have acute, subacute, or chronic presentations (Table 135.1). Myopathies affect proximal or distal muscle groups; some of them also affect heart muscle, leading to cardiomyopathy [1]. Many myopathies are inherited disorders (Table 135.2); in an increasing number of disorders, the genetic background and the abnormal or missing muscle protein have been revealed during the last decade. An updated gene table is published online [2]. There is also a gene table updated for 2012 and published in *Neuromuscular Disorders* [3]. Muscle diseases are rare, with a prevalence of approximately 50 per 100,000. Myopathy is more common in females than in males, although Duchenne muscular dystrophy is found only in males because of an X-linked inheritance.

Muscular Dystrophies

Muscular dystrophies are inherited disorders of muscle due to abnormal structural muscle proteins, for example, dystrophin in Duchenne muscular dystrophy and sarcoglycans, calpain, and dysferlin in different limb-girdle dystrophies [2,3]. They are characterized by progressive course and early onset.

Congenital Myopathies

Congenital myopathies form a clinically heterogeneous group characterized by findings on muscle biopsy. They are slowly progressive or nonprogressive and usually are manifested in the neonatal period.

Metabolic Myopathies Including Mitochondrial Myopathies

Metabolic myopathies form a clinically heterogeneous group of muscle disorders resulting from inherited defects in intracellular energy production. They may be manifested as cramps and myoglobinuria. Patients with cramps and myoglobinuria often have disorders in the glycogen or lipid metabolism pathways. They may be asymptomatic at rest, but symptoms develop after exercise. Mitochondrial myopathies may be a part of a neurologic syndrome often involving the central nervous system.

Inflammatory Myopathies

Inflammatory myopathies are characterized by inflammatory changes in the muscle and are associated with infections

or an immunologic process. They are divided into polymyositis, dermatomyositis, and inclusion body myositis [4]. The course is acute or subacute and is almost always associated with an elevated serum creatine kinase (CK) level.

Drug-Induced and Endocrine Myopathies

Drug-induced myopathies are caused by different drugs, for example, colchicine, azidothymidine (AZT), chloroquine, hydroxychloroquine, and corticosteroids. Myopathy due to intake of statins, the cholesterol-lowering agents, has been reported [5]. Endocrine myopathies include both hyperthyroid and hypothyroid myopathies as well as myopathy due to hyperparathyroidism.

Myotonic Syndromes

A number of disorders are associated with clinical or electrical myotonia. The myotonic disorders are divided into myotonic dystrophies and “pure” myotonia [6]. The myotonias are inherited disorders due to alterations in ion channels in the muscle and seldom give rise to persistent muscle weakness. Myotonic dystrophy (MD 1) or Steinert disease exists in a congenital and an adult form. Individuals with myotonic dystrophy may not notice any problems until adolescence or early adult life [7]. The first symptom may be difficulty in releasing an object due to myotonia. Progressive weakness with onset in distal muscles follows. The genetic explanation to MD 1 is an expansion of a CTG repeat in chromosome 19 (*DMPK* gene). The gene encodes a protein kinase that occurs in different tissues, leading, for example, to cardiomyopathy. The clinical affection is correlated to the number of repeats, and the number of repeats increases between generations, leading to a clinical anticipation. There is also a more rare form with later onset, a slower course, and proximal muscle weakness (MD 2). The genetic background to MD 2 is a CCTG repeat in chromosome 3 (*ZNF9* gene) [8].

Symptoms

Muscle weakness, most often affecting proximal muscles, is the cardinal symptom. Almost all myopathies affect the proximal muscles to the greatest extent. Another prominent symptom is muscle fatigue. The earliest symptoms are often related to weakness of the hip and proximal leg muscles; patients experience difficulty in rising from a chair and often require support of their arms. Compensation for leg extensor weakness by bracing of the legs with the hands and climbing with the hands on the legs when rising to a standing position is known as the Gower maneuver. Walking up and down stairs may be difficult because of quadriceps and hip extensor weakness, respectively. Weakness of proximal muscles in the upper extremities can be manifested as fatigue or inability to perform overhead tasks, such as hair brushing, brushing teeth, and lifting objects to elevated shelves.

In hereditary distal myopathies [9] and inclusion body myositis, the distal muscle weakness leads to footdrop and ankle instability as well as difficulty with manual tasks, such as turning doorknobs and opening jars.

Pain is not a common symptom in myopathies. However, inflammatory and metabolic myopathies are associated with

Table 135.1 Myopathic Disorders

Adrenal, steroid
Pituitary

Drug-Induced/Toxic Myopathies **Myotonic Syndromes**

Myotonic dystrophy (DM type 1)
Myotonic dystrophy, proximal type (DM type 2)
Chloride channel myotonia (myotonia congenita Thomsen)
Sodium channel myotonia (paramyotonia congenita)
Eulenburg, hyperkalemic periodic paralysis)
Calcium channel disorders (hypokalemic periodic paralysis)
Potassium channel disorders (hypokalemic periodic paralysis)
Schwartz-Jampel
Drug induced

Table 135.2 Myopathic Disorders: Major Forms of Inheritance

Disorder	Inheritance
Duchenne muscular dystrophy	X-linked recessive
Becker muscular dystrophy	X-linked recessive
Facioscapulohumeral dystrophy	Autosomal dominant
Scapuloperoneal dystrophy	X-linked dominant
Limb-girdle dystrophy	Autosomal recessive/ dominant
Oculopharyngeal dystrophy	Autosomal dominant
Distal myopathy/muscular dystrophy	Autosomal dominant/ recessive
Congenital muscular dystrophy	Autosomal recessive/ dominant/sporadic
Congenital myopathies	Autosomal recessive
Myotonic syndromes	Autosomal dominant
Metabolic myopathies	Autosomal dominant/ recessive, X-linked recessive

Modified from Dumitru D. *Electrodiagnostic Medicine*. Philadelphia, Hanley & Belfus, 1995:1067.

pain. Exercise-induced muscle pain suggests a metabolic myopathy. The pain has an aching, dull, and crampy quality and is usually poorly localized. An exercise-induced weakness suggests a neuromuscular junction disorder. Symptoms of hypoventilation and cardiac failure should be considered.

Physical Examination

A general examination is performed to assess for signs of cardiac failure and rashes found in dermatomyositis. Muscle atrophy assessment and testing of muscle strength are central and should involve examination of proximal and distal muscles in all extremities as well as facial muscles and neck flexors and extensors. Hip girdle muscles are best isolated for strength testing while the patient is in the supine and prone positions. The abilities of walking, rising from a chair (or floor in pediatric patients), and stepping onto a low chair are often helpful in evaluating leg weakness. Examination of the shoulder may reveal winging of the scapula, a characteristic finding in facioscapulohumeral muscular dystrophy. Facial weakness and temporalis muscle wasting are also present in facioscapulohumeral muscular dystrophy and in myotonic dystrophy.

Range of motion at joints should be examined because contractures may have marked functional effects. Reflexes should be normal or decreased proportional to muscle weakness in myopathies. Abnormalities on sensory testing suggest involvement of sensory nerves (i.e., a neuromuscular disorder).

Functional Limitations

The most common functional limitations are related to the prominent symptom of proximal weakness, which can have a marked effect on transfers, ascending and descending stairs, and ambulation. In severe myopathies, patients may be restricted to wheelchair mobility. Proximal upper extremity weakness can interfere with activities of daily living, such as dressing, grooming, and cooking. Fatigue is common secondary to the increased effort required with weakened muscles. Cardiac failure and respiratory insufficiency requiring ventilation can result in difficulty with daily activities and increased fatigue. The dysphagia involved in some myopathies may make eating time-consuming and difficult.

Diagnostic Studies

The serum CK concentration is the most important test in myopathies. Patients with Duchenne muscular dystrophy may have very high CK values. Serum CK concentration is usually elevated in inflammatory myopathies and metabolic myopathies. It is often normal or nearly normal in congenital myopathies.

Exercise, especially if it is strenuous or performed in a sedentary individual, can cause marked CK elevation. Thus, patients should be advised to abstain from strenuous exercise for 5 days before serum CK testing. CK concentration may also be elevated in neuromuscular disorders, such as motor neuron disease.

Nerve conduction studies are important in cases of suspected myopathy. Sensory and motor nerve conduction studies are usually normal. However, distal compound muscle

action potentials may be reduced. Exceptions include patients with inclusion body myositis (30% have a sensory or sensorimotor polyneuropathy) [4]. In cases with abnormal nerve conduction velocities, coexisting neuropathies such as diabetic polyneuropathy should be considered.

The electromyographic examination is helpful in the evaluation of myopathies. Primarily, the size of motor units is decreased by the dysfunction or loss of individual muscle fibers, leading to motor unit action potentials that characteristically have decreased duration, decreased amplitude, and increased phases in contrast with the neuropathic motor unit action potential findings. In addition, denervating potentials (fibrillations and positive sharp waves) occur in many myopathic disorders.

Muscle biopsy is often useful in the diagnosis of myopathy. The selection of muscle for biopsy is important because a muscle that is end stage is likely to show only fibrotic replacement of muscle tissue, and an unaffected muscle may be normal. In an acute myopathy, it is best to select a muscle for biopsy that is clinically weak; in a chronic myopathy, it is preferable to select a muscle that is only mildly weak. The muscle selected should not have been sampled by needle electromyography, which may result in temporary inflammation. The pathologist, to investigate possible causes, performs specific histochemical and immunohistochemical stains and occasionally electron microscopy on the specimen.

Magnetic resonance imaging may be an additional diagnostic tool in clinical practice. The pattern of muscle involvement is often specific for the different entities [10].

Genetic testing is nowadays routine in the evaluation of many of the muscular dystrophies and is also useful in the evaluation of other chronic myopathies. With similar phenotypes, such as limb-girdle muscular dystrophy, the only way to accurately diagnose the condition is by genetic testing. A helpful resource is the gene table published online [2].

Differential Diagnosis

- Motor neuron disease
 - Amyotrophic lateral sclerosis
 - Late-onset spinal muscular atrophy
- Neuromuscular junction disorders
 - Myasthenia gravis
 - Lambert-Eaton myasthenic syndrome
- Motor neuropathies
 - Demyelinating motor neuropathies, such as multifocal motor neuropathy and diabetic amyotrophy
 - Spinal stenosis or myelopathy
 - Parkinson disease
 - Poliomyelitis, postpoliomyelitis syndrome

Treatment

Initial

Of great importance is an initial detailed explanation to the patient and relatives. Patients are informed that they must not exert themselves to the point of exhaustion. Referral to the Muscular Dystrophy Association is helpful for education and support of the patient.

Steroids are often effective in the treatment of inflammatory myopathies (as are other immunosuppressants) and have been shown to slow progression in some muscular dystrophies. In a recent Cochrane report [11], corticosteroids were shown to improve muscle strength and function in Duchenne muscular dystrophy in the short term. Carnitine is used in lipid storage myopathies. Much work is now devoted to development of new therapeutic strategies, including gene [12] and stem cell [13] therapies. Otherwise, the only therapeutic option is symptomatic treatment (e.g., pain treatment with different analgesics).

Rehabilitation

Physical therapy and occupational therapy are often necessary for gait training and stretching. Assistive devices, such as canes, walkers, and wheelchairs, as indicated in a particular patient, can minimize disability. Assistive devices should be used, preferably after training with a physical therapist. Bracing may be helpful for footdrop.

Adaptive equipment may be prescribed to assist a patient to perform daily activities. Home adaptations, such as tub bars and entrance ramps, may be of great assistance to patients with proximal muscle weakness.

Exercise can help maintain joint range of motion. There has been debate about whether patients with muscle disorders benefit from exercise training. There is an increasing knowledge on the effect of exercise training in different muscle disorders [14,15]. High-resistance training at submaximal level seems to be beneficial in slowly progressive disorders in the short term. In rapidly progressive disorders, such as Duchenne muscular dystrophy, high-resistance training is questionable [14]. On the basis of this, moderate exercise, not to the point of exhaustion, is preferable. It is important to start exercise training early in the course of the disease so that there are still trainable muscle fibers left.

The common opinion on exercise training in inflammatory myopathies has changed during recent years. Patients with inflammatory myopathies have been strongly advised to avoid exercise. However, results from training studies have shown that exercise training has beneficial effects on muscle function [16].

Procedures

Assisted ventilation, including negative pressure ventilation, noninvasive positive pressure ventilation, and invasive positive pressure ventilation (i.e., endotracheal tube or tracheostomy), may be indicated for patients with insufficient ventilation [17]. Feeding tubes may be necessary for patients with dysphagia due to severe bulbar myopathy.

Surgery

Patients with muscular dystrophies may require contracture release and spine stabilization surgeries.

Potential Disease Complications

Severe myopathies, including muscular dystrophies, can cause restrictive pulmonary disease due to chest wall

muscle weakness and scoliosis. Assisted ventilation, including negative pressure ventilation, noninvasive positive pressure ventilation, and invasive positive pressure ventilation (by endotracheal tube or tracheostomy), may be indicated. Decreased mobility can result from proximal lower and upper extremity weakness. Contractures can be caused by disuse and fibrosis as well as by scoliosis due to paraspinal muscle weakness. Cardiac involvement is present in some forms of muscle disorders [1]. Gastrointestinal symptoms due to smooth muscle involvement are common in patients with muscular dystrophies.

Potential Treatment Complications

Immunosuppression may have associated side effects. Steroid use and decreased mobility may lead to osteoporosis and the subsequent risk of pathologic fractures, and analgesics have well-known side effects. Special attention should be paid to patients undergoing general anesthesia because of the risk of malignant hyperthermia, which is a potentially lethal condition appearing in different myopathies, including a specific disorder with a mutation in the skeletal muscle ryanodine receptor.

Q76.0 Spina bifida occulta
R26.9 Unspecified abnormalities of gait and mobility

Definition

A neural tube defect occurs when the neural tube, the embryologic precursor to the brain and spinal cord, fails to close between the third and fourth weeks of embryogenesis. Neural tube defects are a subset of central nervous system congenital anomalies leading to varying degrees of neurologic impairment from complete failure of neurulation

to spina bifida occulta, a posterior vertebral defect without protrusion of neural tissue. Myelomeningocele (MMC), a form of spina bifida cystica, is the most common spinal dysraphism. MMC occurs when the meninges and the spinal cord project through a vertebral defect, forming a sac most commonly located in the lumbosacral region.

The etiology of neural tube defects is multifactorial. Genetic factors have been implicated; there is a 4% risk of recurrence of MMC after having one affected child [1,2]. Associated environmental factors include low socioeconomic status, parental occupation, maternal diabetes mellitus, maternal hyperthermia, maternal obesity, and drug exposures, such as to valproic acid [1]. Since the mandatory fortification of grain products with folate in the United States in 1998, the prevalence rate of spina bifida declined 31% to a rate of 3.49 per 10,000 [1]. The highest prevalence, in the United States, is among women of Hispanic ethnicity [1].

Symptoms

Neurologic

Clinical presentation (Table 136.1) will vary by the extent of involvement of sensory, motor, and autonomic nerves. Dysphagia, aspiration, stridor, vocal cord paralysis, nystagmus, spasticity, bradycardia, and sleep apnea are all symptoms of *brainstem dysfunction*. A high index of suspicion is

sometimes necessary for early assessment and management because severe apnea may lead to respiratory arrest, which could in turn result in death.

The symptoms of *hydrocephalus* will vary by age. In an infant, symptoms include lethargy, poor appetite, vomiting, accelerated head enlargement, bulging anterior fontanelle, dilated scalp veins, spasticity, and clonus. In an older child, headache is a prominent symptom. Mechanical obstruction of a ventriculoperitoneal shunt (VPS) is manifested acutely with signs of hydrocephalus. VPS infections are associated with fever, headache, and meningismus. Adults with VPS can develop chronic idiopathic headaches.

Tethered cord syndrome can result in progressive scoliosis, decline in lower extremity strength, development of lower extremity contractures, spasticity, change in gait or urinary symptoms, low back pain, and skin ulcers. Patients with spina bifida occulta may present to providers with tethered cord syndrome symptoms beginning during adulthood [3].

A noted increase in spasticity can be caused by hydrocephalus, syringomyelia, tethered cord, urinary tract infection, and decubitus ulcers. Seizures may be common in children with MMC.

Orthopedic

Symptoms from progressive scoliosis can include pain, cardiopulmonary dysfunction, and severe disability interfering

Table 136.1 Clinical Presentation and Functional Considerations of Myelomeningocele by Neurosegmental Level

	Neurosegmental Levels			
	T6-12	L1-L3	L4-L5	S1-S4
Muscles involved	Abdominal muscles, trunk flexors and extensors	Iliopsoas (L1-L3) Hip adductors (L2-L4) Quadriceps (L2-L4)	Hip adductors (L2-L4) Quadriceps (L2-L4) Gluteus medius (L4-S1) Gluteus maximus (L5-S1) Hamstring (L5-S2) Tibialis anterior (L4-L5) Peroneal (L5-S1) Tibialis posterior (L4-L5) Toe extensors (L5-S1) Toe flexors (L5-S3) Foot intrinsics (L5-S3)	Gluteus medius (L4-S1) Gluteus maximus (L5-S1) Hamstring (L5-S2) Peroneal (L5-S1) Gastrocnemius (S1-S2) Toe extensors (L5-S1) Toe flexors (L5-S3) Foot intrinsics (L5-S4)
Orthopedic complications				
Spine	Kyphosis Scoliosis	Scoliosis Lordosis	Scoliosis Lordosis	
Hips	Hip flexion contractures	Hip dislocation Hip flexion and adduction contractures	Hip dislocation Hip flexion contractures	
Legs	Knee flexion contractures	Knee flexion contractures		
Feet	Equinus	Equinus	Calcaneovarus Calcaneus	Cavus
Ambulatory potential	Can ambulate with equipment; however, poor long-term probability	Household ambulation (may cease ambulation during second decade of life)	Community ambulation	Community ambulation
Equipment needs	Wheelchair TLSO HKAFO KAFO RGO Standers	Wheelchair RGO KAFO Dynamic standers Hip abduction splint	Forearm crutches Walkers KAFO AFO	AFO SMO

AFO, ankle-foot orthosis; HKAFO, hip-knee-ankle-foot orthosis; KAFO, knee-ankle-foot orthosis; RGO, reciprocating gait orthosis; SMO, supramalleolar orthosis; TLSO, thoracolumbar-sacral orthosis.

with sitting balance and ambulation. Hip deformities, including contractures and dislocations, may result in popping sensation, leg length discrepancy, and pain. Pelvic obliquity can lead to progression of scoliotic curve and difficulties with sitting and positioning. Presence of knee flexion or extension contractures may interfere with functional tasks, such as transfers. Foot deformities are common and may depend on which spinal segments are affected. Pathologic fractures in the lower limbs may be manifested with localized erythema and swelling [4]. Musculoskeletal pain in the shoulder area may be extremely common in wheelchair users, especially in adult patients.

Urinary

Patients may present with urinary retention or incontinence from neurogenic bladder. Urinary tract infections can be associated with fever, changes in urinary control like new-onset leakage between catheterizations, and change in urine quality (color, foul odor, or sediment).

Gastrointestinal

Stool incontinence and constipation are symptoms of neurogenic bladder. Chronic constipation may lead to incontinence due to overflow.

Endocrine

Short stature due to growth hormone deficiency is the most common endocrine symptom [5].

Reproductive

Many men with MMC are infertile [6]. Fertility among women with MMC is thought to be normal [7]. Change in urologic status (i.e., new-onset incontinence) or back pain may be a presenting sign of pregnancy or labor.

Pulmonary

Brainstem dysfunction associated with Chiari II malformation can lead to hypoventilation, apnea, and respiratory failure. Restrictive lung disease can be seen with severe progression of neuromuscular scoliosis. In thoracic-level MMC, partial innervations of abdominal and intercostal musculature may result in respiratory insufficiency.

Cardiovascular

Lower extremity swelling may be due to positional edema or lymphedema. There is evidence showing increased prevalence of lymphedema [8]. Hypertension may be prevalent as well with associated metabolic syndrome and early-onset arteriosclerosis from sedentary lifestyle and obesity.

Allergy and Immunology

There is an increased prevalence of latex allergy. Careful precautions should be taken as a severe reaction can include angioedema and anaphylaxis. This can be life-threatening.

Dermatology

Patients with MMC are at risk for pressure ulcers because of insensate skin, incontinence, impaired mobility, orthopedic abnormalities, and orthoses.

Nutrition

Obesity is common, especially in older adolescents and adults. Significant dysphagia, on the other hand, may lead to failure to thrive and difficulty in gaining weight from brain-stem dysfunction.

Psychosocial

Difficulties with motivation and academic performance may be reported by parents. Depression may be common in older adolescents and adults [9].

Physical Examination

A full physical examination should be performed and will vary on the basis of the level of the lesion. Particular focus for the physiatrist lies in the neurologic and musculoskeletal examination and its relation to functional status. Criteria for assessment of motor level in patients with MMC should be used (Table 136.2). Examination should include assessment of the cranial nerves, mental status, motor strength, sensation, reflexes, range of motion in joints, muscle tone, spinal alignment, and gait. Developmental screening includes assessment of gross and fine motor, language, and cognitive abilities. Anthropometric measurements should be monitored in the MMC population because of a high incidence of decreased height or linear length from associated musculoskeletal deformities [10]. Arm span measurements allow a more accurate assessment of body mass index [10]. The Centers for Disease Control and Prevention growth charts used for able-bodied children may not provide all the information necessary for assessment of appropriate growth and nutrition. Evaluation for skin breakdown and for cutaneous midline lesions of the spine, which may signal an underlying form of occult dysraphism, should be performed. The patient's equipment should be routinely evaluated.

Functional Limitations

Functional limitations vary by the degree of associated neurologic impairments and orthopedic abnormalities. Children with MMC generally have delay in ambulation [11]. The strength of the iliopsoas, quadriceps, and gluteus medius muscles is an important predictor of ambulatory potential. In general, patients with thoracic lesions are wheelchair dependent. Patients with upper lumbar lesions usually ambulate household distances with variable wheelchair dependency. Patients who have lower lumbar and sacral lesions ambulate longer community distances. These patients may still require some bracing or assistive devices.

Other factors, such as presence of hydrocephalus, seizures, muscle tone, contractures, fractures, weight, cognition, and motivation, among others, have been implicated with ambulation and mobility [11,12].

Table 136.2 International Myelodysplasia Study Group: Criteria for Assigning Motor Levels

Motor Level	Criteria for Assigning Motor Levels	Functional Movement Noted
T10 or above	Determined by sensory level and/or palpation of abdominal muscles	
T11	Trunk extensors (thoracic and lumbar)	
T12	Abdominal and paraspinal muscles provide some pelvic control. Hip hiking from the quadratus lumborum may also be present.	Hip hike
L1	Grade 2 weak iliopsoas , quadratus lumborum	Hip hike
L1-2	Exceeds criteria for L1 but does not meet L2 criteria	
L2	Meets or exceeds criteria for L1 + Grade 3 iliopsoas Grade 3 sartorius Grade 3 hip adductors (adductor magnus, brevis, longus; pectineus; gracilis)	Hip flexion Hip adduction
L3	Meets or exceeds the criteria for L2 + Grade 3 quadriceps	Knee extension
L3-4	Exceeds criteria for L3 but does not meet L4 criteria	
L4	Meets or exceeds the criteria for L3 + Grade 3 medial hamstrings Grade 3 tibialis anterior A weak peroneus tertius may also be seen.	Medial knee flexion Ankle dorsiflexion
L4-5	Exceeds criteria for L4 but does not meet L5 criteria	
L5	Meets or exceeds the criteria for L4 + Grade 2 gluteus medius Grade 3 lateral hamstring (biceps femoris) Grade 3 tibialis posterior	Hip abduction Knee flexion Ankle inversion
L5-S1	Exceeds criteria for L5 but does not meet S1 criteria	
S1	Meets or exceeds the criteria of L5 + Grade 3 gluteus medius Grade 2 gastrocnemius/soleus complex	Hip abduction Ankle plantar flexion
S1-2	Exceeds criteria for S1 but does not meet S2 criteria	
S2	Meets or exceeds the criteria for S1 + Grade 4 gluteus maximus Grade 3 gastrocnemius/soleus complex	Hip extension Ankle plantar flexion
S2-3	All of the lower limb muscle groups are of normal strength (grade 4 in 1-2 muscle groups) Also includes normal-appearing infants who are too young to be bowel and bladder trained	
"No loss"	Meets all of the criteria for S2-3 + has no bowel or bladder dysfunction	

Bold text indicates main muscle tested.

Diagnostic Studies

Prenatal

Elevated serum levels of α -fetoprotein detected in the second trimester suggest a neural tube defect. Fetal ultrasonographic imaging and magnetic resonance imaging can aid in determining prognosis and parental decision-making [13]. Amniocentesis may show elevated levels of α -fetoprotein and acetylcholinesterase, also consistent with a neural tube defect.

Postnatal

At birth, the determination of neurologic status is clinical. A head ultrasound examination is performed to assess for ventricular size. Echocardiography can be performed before surgical repair to rule out congenital heart disease. Cranial or spinal ultrasound examination can be used for noninvasive assessment of neurologic status in an infant. Beyond infancy, magnetic resonance imaging is performed to assess the spinal cord, and computed tomography is used to assess for hydrocephalus. A shunt series can be

performed if there is concern for shunt malfunction. A VPS tap may be performed to rule out infection. Plain film radiography or computed tomography is used when there is concern for a joint or spine deformity or pathologic fracture.

Urologic studies include renal and bladder ultrasonography, voiding cystourethrography, urodynamic studies, DMSA nuclear scan, and postvoid residual measurement [14]. Cystoscopy is performed for bladder cancer surveillance, especially if the patient has undergone bladder augmentation procedures [15]. Routine blood work may include a complete blood count, comprehensive metabolic profile, lipid panel [16], 25-hydroxyvitamin D level, and cystatin C level [14]. Depending on clinical presentation, other diagnostic studies may include determination of endocrine hormone levels and prealbumin concentration, electroencephalography, dual-energy x-ray absorptiometry scan, polysomnography, and latex allergy assay. Throughout childhood and adulthood, health care providers should continue to perform routine health maintenance. Neuropsychological testing should be performed before entrance into school.

Differential Diagnosis

Alternating hemiplegia of childhood
 Arthrogryposis
 Cerebral palsy
 Charcot-Marie-Tooth disease
 Congenital hypothyroidism
 Congenital myopathies
 Congenital neuropathies
 Currarino syndrome
 Hereditary spastic paraparesis
 Inborn error of metabolism
 Intracranial tumor
 Ischemic or hemorrhagic stroke
 Multiple vertebral segmentation defects
 Myotonia congenita
 OEIS complex (omphalocele, exstrophy of the cloaca, imperforate anus, and spinal defects)
 Poliomyelitis
 Sacrococcygeal teratoma
 Spinal epidural abscess
 Spinal cord hemorrhage
 Spinal cord infarct
 Spinal cord injury
 Spinal muscle atrophy
 Spinal tumor
 VACTERL association (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities)

Treatment

Initial

Surgical closure of MMC within 48 hours is customary. Fetal surgery can be performed before 26 weeks of gestational age. Lower incidences of hindbrain abnormalities and shunt-dependent hydrocephalus as well as improved motor outcomes have been reported for in utero compared with postnatal surgical closure [17]. However, fetal surgery has not shown improvement in lower urinary tract function [18].

First-line management of hydrocephalus is placement of a VPS. Endoscopic third ventriculostomy combined with choroid plexus cauterization represents an alternative technique by addressing both the communicating and noncommunicating mechanisms of hydrocephalus without introducing shunt dependency [19].

Infants who are unable to void or who have large postvoid residuals should begin clean intermittent catheterization programs. Children can be taught to perform clean intermittent catheterization as early as 5 years of age, although it may take longer because of the high executive function impairments related to hydrocephalus. Patients with detrusor-sphincter dyssynergia or hydronephrosis may be treated with anticholinergic medications. Children with vesicoureteral reflux are often prescribed prophylactic antibiotics. Various treatments exist for hyperactive sphincter function.

A bowel management program may consist of stool softeners, bulking agents, suppositories, digital stimulation, manual removal, or enemas. Clinicians often recommend performing bowel programs after a meal to take advantage of the gastrocolic reflex.

An acute change in the respiratory status of a patient may warrant posterior fossa decompression or treatment

of hydrocephalus. If this is unsuccessful, tracheostomy and long-term mechanical ventilation may be considered.

Other treatment modalities may include antiepileptics, growth hormone or gonadotropin-releasing hormone analogue treatment, bisphosphonates, and calcium and vitamin D. Recommendations for daily physical activity and dietary management must be included. Genetic counseling and appropriate folic acid supplementation are advised for affected women considering pregnancy. Current guidelines for folic acid supplementation are 0.4mg/day for any woman of childbearing age and 4mg/day for women with a previous neural tube defect pregnancy or who are at high risk [20].

Rehabilitation

Rehabilitation and comprehensive medical care for patients with MMC involve a family-centered approach by a multidisciplinary team to include physiatrists, physical therapists, occupational therapists, speech-language pathologists, recreational therapists, behavioral psychologists, neuropsychologists, teachers, social workers, and child life specialists in collaboration with other physicians and surgeons. Educational needs should be assessed for implementation of an individualized education plan or 504 plans. Vocational rehabilitation should be considered as well. Educating the patient about the condition and promoting independence in self-care and maintenance of mobility status are essential to improve quality of life and to decrease preventable conditions [21]. Advancements in the medical and surgical management of children with MMC, especially after 1975, have resulted in increased life expectancy [22,23]. Survival to 16 years of age is estimated at 54% for those treated before 1975 and 85% for those treated after 1975 [22]. If a shunt is in place, there is a risk of decreased survival after 34 years of age [22]. Effective transition to adult health care providers remains an area of further research.

The general goals of the treatment plan include maintaining range of motion, strengthening, promoting functional independence through development, encouraging weight-bearing exercises, and maximizing mobility and cardiovascular fitness. It is important to establish a home exercise program. Equipment should be optimized for functional level and modified for proper fit. Wheelchair users may require pressure mapping. A reciprocating gait orthosis may be considered in higher level lesions and requires active hip flexion for use. Other equipment may include walkers, crutches, canes, standers, parapodiums, resting splints, adaptive equipment, and orthoses, depending on the functional level. Patients may cease ambulation during the second year of life as a result of weight gain and axial growth [11].

Procedures

Spasticity may be treated with onabotulinum toxin or phenol injections. Functional electrical stimulation may be beneficial. Nonoperative management of various orthopedic abnormalities may include bracing and casting. Management of neurogenic bladder may include intravesical onabotulinum toxin injections or anticholinergics.

Surgery

Children with a VPS may develop obstruction requiring shunt revision. Studies show that shunted patients,

presenting with shunt malfunction, may be freed from shunt dependence by an endoscopic third ventriculostomy, instead of a shunt revision [19]. A symptomatic Chiari II malformation warrants craniocervical decompression. Severe brainstem involvement may lead to placement of a gastrostomy tube and tracheostomy because of respiratory insufficiency and dysphagia. Tethered cord syndrome with neurologic decline may require surgical intervention for release. Surgical options for spasticity and contracture management include contracture release, tendon lengthening, joint capsule release, targeted rhizotomy, and intrathecal baclofen pump placement.

Patients who have progressive scoliosis should undergo a spinal arthrodesis or fusion. Surgical treatment of hip contractures and dislocations is controversial [24]. Surgery for hip dislocation may not improve walking ability and should mostly be considered in unilateral dislocation in lesions below L4 [24]. Surgical correction of various foot deformities is performed to allow a functional position for ambulation and to prevent pressure ulceration.

Surgical procedures for neurogenic bladder and bowel include an artificial urinary sphincter, bladder augmentation, bladder neck sling or closure, continent catheterizable stoma, vesicotomy, antegrade continence enema, and colostomy.

Potential Disease Complications

MMC is associated with Arnold-Chiari type II malformation, a posterior fossa malformation in which the caudal vermis, cerebellar tonsils, and medulla can herniate through the foramen magnum, resulting in obstructive hydrocephalus (Fig. 136.1). As a result, brainstem dysfunction can occur. In spinal dysraphisms, the spinal cord is generally anatomically fixed at the site of the anomaly after neonatal repair. Neurologic decline can occur secondary to traction, or tethering, on the cord from aggravating factors such as growth spurts, trauma, and existing deformities. An increase in spasticity can be caused by hydrocephalus, syringomyelia, tethered cord, urinary tract infection, and decubitus ulcers. Seizures may be common in children with MMC. Other complications may include supratentorial cerebral malformations and visuospatial dysfunction.

Scoliosis, kyphosis, or lordosis may result from muscle imbalances and congenital spinal deformities. Vertebral congenital abnormalities are associated with MMC and can cause worsening of spinal deformities. Orthopedic deformities of hips, knees, and ankles, including contractures and dislocations, are related to positioning and muscle imbalance. Some orthopedic deformities, such as foot deformities and early hip dislocation, may be congenital. Others, such as late hip subluxation, contractures, osteoporosis, and fragility fractures, may be acquired. Foot deformities are common in all MMC levels. Charcot joints from poor sensation, pressure, weight bearing, and repetitive microtrauma can be seen.

Neurogenic bladder may lead to chronic kidney disease from vesicoureteral reflux, recurrent urinary tract infections, and urinary incontinence or retention. Patients with neurogenic bladder and chronic use of indwelling urinary catheters or bladder augmentation procedures may be at higher risk for development of bladder cancer. Early surveillance is recommended.

FIGURE 136.1 T1-weighted magnetic resonance image of the brain: Arnold-Chiari type II malformation with tonsillar displacement, of more than 3 mm, through the foramen magnum (hindbrain herniation), resulting in obstructive hydrocephalus.

Neurogenic bowel may lead to fecal impaction or incontinence. Early-onset diverticulosis and complications with megacolon have been reported as well.

Hypothalamic-pituitary dysfunction may be present because of hydrocephalus or other central nervous system abnormalities. However, underdevelopment of the lower limbs, from neurogenic atrophy, and spinal deformities present in MMC also play a role in short stature. Other reported complications include precocious puberty, cryptorchidism, sexual dysfunction, and male infertility. Fertility in women is mostly normal; however, a higher risk of having a child with MMC has been reported. Instead of 400 µg of folic acid recommended for the general female population, these patients should supplement with 4 mg of folic acid during childbearing age.

Lack of sensation, orthopedic deformities, equipment or medical device malfunction (including poor fit), and obesity may lead to pressure ulcers. Wound healing may be impaired because of autonomic dysfunction. Chronic non-healing ulcers may require specialized medical or surgical management. Chronic occult osteomyelitis may be seen.

Obesity rates are higher among adults with spina bifida compared with the general population, especially affecting adult women [25]. This can have an impact on mobility and equipment needs.

Patients with thoracic-level lesions and hydrocephalus are at greater risk for cognitive impairment [26]. Other factors implicated in intellectual outcome include incidence of shunt revision and infection, epilepsy, and associated cerebral malformations [27]. Common findings include neuropsychological deficits in visual perception, academic difficulties in mathematics, and better verbal skills than written skills [26]. Mood disorders, such as depression, may be common in older adolescents and adults [9].

Potential Treatment Complications

VPS complications can include obstruction, infection, and intellectual delay. Other treatment complications include deterioration in neurologic status, cerebrospinal fluid leak, surgical wound dehiscence or infection, spinal cord injury, pain, osteoporotic fractures during therapy, development of latex allergy, and death.

ICD-10 Codes

- G83.4** Cauda equina syndrome with neurogenic bladder
- N31.2** Flaccid neuropathic bladder, atonic neuropathic bladder
- N31.8** Other neuromuscular dysfunction of bladder
- N31.9** Neuromuscular dysfunction of bladder, unspecified
- N36.44** Muscular disorders of urethra, bladder sphincter dyssynergy
- N32.9** Bladder disorder, unspecified
- N32.89** Other specified disorders of bladder

Definition

The term *neurogenic bladder* describes a process of dysfunctional voiding as the result of neurologic impairment. This can interfere with urine storage at low bladder pressures,

disrupt voluntary coordinated voiding, and lead to varying degrees of incontinence. Neurologic control of bladder function is at multiple levels throughout the central nervous system and subject to multiple pathophysiologic processes. Voiding dysfunction occurs in most of the neurologically impaired patients [1].

The micturition reflex center has been localized to the pontine mesencephalic reticular formation in the brainstem [2,3]. Efferent axons from the pontine micturition center travel down the spinal cord in the reticulospinal tract to the detrusor motor nuclei located in the S2, S3, and S4 segments in the sacral gray matter (vertebral levels T12 to L2). Parasympathetic nerves take their origin from nuclei at the intermediolateral gray column of the spinal cord at S2, S3, and S4 and travel by the pelvic nerve and pelvic plexus to ganglia in the bladder wall. The predominant parasympathetic nerve root supplying the bladder is usually S3. Acetylcholine is released from the postganglionic nerves, which in turn excites muscarinic receptors [4,5].

Preganglionic sympathetic neurons originate in the intermediolateral gray column of the spinal cord from spinal segments T10 to L2. These nerves course to the sympathetic chain ganglion and through the pelvic plexus to the bladder neck and fundus of the bladder. Receptors at the bladder neck are primarily α -adrenergic [6], stimulation of which results in closure of the internal sphincter during urinary storage and, in men, during ejaculation as well. In contrast to the bladder neck, the fundus of the bladder is populated with β -adrenergic receptors, which contribute to bladder relaxation (and therefore urinary storage) during sympathetic activation.

The external urethral sphincter (striated muscle, voluntary) surrounds the membranous urethra and extends up and around the distal part of the prostatic urethra. The pudendal nerves, which innervate the external sphincter, take their origin from the somatic motor nuclei in the anterior gray matter of the sacral cord (conus, S2-S4); however, it is the S2 spinal segment that provides the principal motor contribution. Toe plantar flexors also have S1 and S2 innervations. Thus, the preservation of toe plantar flexors after spinal cord injury suggests that the external urethral sphincter is intact.

The central control of the bladder is a complex multi-level process. Advances in functional brain imaging have allowed research into this control in humans. The regions

of the brain that have been implicated in the central control of continence include the pontine micturition center, periaqueductal gray, thalamus, insula, anterior cingulate gyrus, and prefrontal cortices. The pontine micturition center and the periaqueductal gray are thought to be crucial in the supraspinal control of continence and micturition. Higher centers, such as the insula, anterior cingulate gyrus, and prefrontal regions, are probably involved in the modulation of this control and cognition of bladder sensation. Further work should aim to examine how the regions interact to achieve urinary continence [7].

Symptoms

The symptoms of neurogenic bladder have a wide spectrum of presentation and include urinary incontinence, urinary retention, suprapubic or pelvic pain, incomplete voiding, paroxysmal hypertension with diaphoresis (autonomic dysreflexia), recurrent urinary tract infections, and occult deterioration in renal function. The symptoms vary according to the level of spinal cord injury and pathophysiologic basis of the neurologic disorder.

Abnormalities in the midbrain (e.g., Parkinson disease) lead to detrusor hyperreflexia due to loss of dopamine. Lesions in segmental areas of the spinal cord lead to detrusor-sphincter dyssynergia (DSD). Cortical lesions (lesions above the pontine micturition center) usually result in loss of voluntary inhibition of the micturition reflex. Lesions in the forebrain, such as cerebrovascular accidents with change in blood flow to the cingulate gyrus, can lead to hyperreflexic bladder because of reduced dopamine D_1 with increased glutamate activity. Thus, the cingulate gyrus plays an important role in urine storage. Patients with Parkinson disease have less severe urinary dysfunction with little evidence of internal or external sphincter denervation. By contrast, in multiple system atrophy, patients have more symptoms and wide-open bladder neck. The result is a hyperreflexic bladder with coordinated (synergic) sphincter function [8,9]. In the absence of outflow obstruction (e.g., urethral stricture, benign prostatic hyperplasia, large uterine leiomyoma, fecal impaction), complete bladder evacuation with some incontinence is the outcome. The findings of postmicturition residuals of more than 100 mL, detrusor-external sphincter dyssynergia, and open bladder neck at the start of bladder filling, with significant postural hypotension and neurogenic sphincter motor unit potentials, are highly suggestive of multiple system atrophy [8,9]. It seems DSD reported in such patients may be a voluntary contraction of external sphincter to avoid leakage and is therefore not true DSD. The patient can have unstable blood pressure, which is aggravated with a postural change, indicating some degree of autonomic failure. Similarly, after a severe head injury, an autonomic failure can result in unstable postural hypotension and wide-open bladder neck. The insula and anterior cingulate seem to be responsible for the modulation of autonomic function [10].

All lesions from the pons to spinal cord level S2 result in a loss of cortical inhibition and loss of coordinated sphincter activity during reflex voiding. The micturition reflex is without an inhibitory or coordinated control from higher centers. This results in a hyperreflexic bladder with dyssynergic sphincter function, which often results in incomplete voiding and high bladder pressures; it can lead to vesicoureteral reflux. Urinary

retention from functional obstruction occurs, and overflow incontinence may occur with an overdistended bladder.

Spinal cord lesions above T5-T6 result in autonomic dysreflexia above the key level (T5-T8) that innervates the splanchnic bed and regulates blood supply to control blood pressure. Accentuated visceral activity (e.g., full bladder, fecal impaction), which causes sympathetically mediated vasoconstriction, is normally inhibited by secondary output (a negative feedback) from the medulla and is countered by vasodilation in the splanchnic bed through the greater splanchnic nerve. Without the proper inhibitory reflexes or control of the splanchnic bed to redistribute circulating blood volume, blood pressure rises sharply. With the carotid bodies and vagal nerves intact, bradycardia results. The full syndrome is characterized by paroxysmal and extreme elevation in blood pressure, facial flushing, perspiration, goose pimples, headache, and some degree of bradycardia. This is virtually always seen in conjunction with detrusor-sphincter dyssynergia [11].

Spinal cord lesions in the conus at S2 or below result in lower motor neuron injury to the bladder and external sphincter. The effect on the bladder is predictable: areflexia. Because the parasympathetic ganglia reside in or near the bladder wall, bladder tone is generally maintained. Bladder compliance therefore tends to decrease with time as a result of neural decentralization (or infection-related fibrosis) [1,12]. The result on the bladder neck and external sphincter is not as intuitive. An atonic synergic sphincter system might be expected; the external sphincter usually retains some fixed tone, although not under voluntary control; and the bladder neck is often competent because of the intact sympathetic innervations (α -adrenergic activity) but is nonrelaxing. Even though bladder pressures are generally low during filling and storage, obstructive physiology is often the case during voiding [1,13]. Overflow incontinence is possible. A small, titrated dose of alpha blockers can maintain some continence and improve voiding.

In the acute phase of injury, most central nervous system lesions result in a temporarily areflexic bladder [14,15]. This phase, termed central nervous system shock, is variable and can last several weeks. Reappearance of knee jerks heralds recovery from the shock phase. The specific patterns of voiding dysfunction with the most common neurologic abnormalities in the chronic phase are detailed in [Table 137.1](#) and [Figure 137.1](#).

Confounding medical problems, such as diabetes and many cardiovascular drugs ([Table 137.2](#)), will profoundly affect bladder function. Patients who catheterize themselves intermittently should be asked about the size of catheter used and whether there is any resistance or trauma during catheterization—clues to the presence of a urethral stricture. Patterns of voiding should be elicited, and changes in voiding habits should be scrutinized. Patients with suprasacral spinal cord injury, for example, often give a history of intermittent stream coinciding with spasticity of their lower extremities, a strong clue to detrusor-sphincter dyssynergia. Spinal cord-injured patients with incomplete lesions can void with excessive Valsalva maneuver and can produce very high intra-abdominal pressures. This can lead to vesicoureteral reflux, upper tract changes, repeated pyelonephritis, and even bladder and kidney stone disease. They therefore need to be monitored frequently with urodynamics and managed

Table 137.1 Patterns of Voiding Dysfunction in Chronic Neurologic Disease

Neurologic Disorder	Detrusor Activity	Striated Sphincter	Comments
Suprapontine	Hyperreflexic	Synergic	
Brain tumor, cerebral palsy			Detrusor-sphincter dyssynergia may occur in those with spinal cord damage; voluntary control may be impaired
Cerebrovascular accident			Voluntary control may be impaired
Delayed central nervous system maturation			Persistence of uninhibited bladder beyond age 2-3 years; enuresis later
Dementia			Voluntary control is impaired
Parkinson disease			Detrusor contractility and voluntary control may be impaired
Pernicious anemia			Bladder compliance may be decreased
Shy-Drager syndrome			Bladder neck remains open; bladder compliance may be decreased; autonomic instability (low blood pressure)
Pons-S1	Hyperreflexic	Dyssynergic	
Anterior spinal cord ischemia			Bladder compliance may be decreased
Multiple sclerosis			Varies with lesions
Myelodysplasia, trauma			Variable
Below S1	Areflexic	Fixed tone	
Acute transverse myelitis			Bladder neck may be closed but nonrelaxing
Diabetes, Guillain-Barré syndrome, herniated intervertebral disc			Usually overdistended bladder
Myelodysplasia, poliomyelitis			Decreased bladder compliance may develop; bladder neck may be open (sympathetic denervation)
Radical pelvic surgery			Bladder neck is open
Tabes dorsalis, trauma			Bladder neck may be closed but nonrelaxing

FIGURE 137.1 Diagrammatic illustration of central nervous system disorders leading to different neurologic manifestations. (From Perkash I. *Incontinence in patients with spinal cord injuries*. In O'Donnell P, ed. *Geriatric Urology*. Boston, Little Brown, 1994.)

appropriately to achieve low-pressure voiding. Approximately 50% of men ultimately have benign prostatic hyperplasia. Thus, even in the case of stable neurologic disease, these men may develop difficulty in voiding from progressive outflow

obstruction. Typical symptoms include nocturia, decreased force of stream, hesitancy, and postvoid dribbling. However, patients with outflow obstruction frequently have irritative voiding symptoms as well. It is important to make sure that these symptoms are not due to symptomatic infection: back pain, suprapubic pain, fever, dysuria, urgency, frequency, or hematuria. These symptoms are not specific and can reflect many of the processes discussed. Their presence must therefore be interpreted according to context.

Physical Examination

General considerations include the level of disability and the capability to use upper and lower extremities. The neurologic examination focuses on the strength and dexterity of the upper extremities and the tone and reflexes of the lower extremities. Neurourologic examination includes perianal sensation for evidence of sacral sparing, anal sphincter voluntary contraction, and bulbocavernosus reflex.

The genitalia are examined for the condition of the penis: whether it is circumcised, its size, and adequacy of the meatus; attention is also paid to the presence of meatal erosion due to an indwelling catheter. In women, it is important to note the appearance of the urethral meatus; this structure erodes quite readily with long-standing catheterization. Pelvic examination will identify confounding factors to voiding dysfunction, such as uterine prolapse or leiomyoma. Rectal examination yields information on anal tone, size of prostate, and presence of fecal impaction. Voluntary contraction of the anal sphincter indicates control over the perineal muscles; in the presence of quadriplegia, it indicates an incomplete central cord-type lesion. To determine voluntary contraction, the clinician places a

Table 137.2 Pharmacologic Action on the Bladder

Drug	Indication	Mechanism	Side Effects and Cautions
Cholinergics Bethanechol	Areflexic bladder	Muscarinic receptor agonists Bladder has M ₂ and M ₃ receptors; M ₃ receptors are responsible for normal detrusor contraction	Bronchospasm, miosis
Anticholinergics Hyoscyamine Oxybutynin Tolterodine Trospium chloride (quaternary amine) Darifenacin Solifenacin	Hyperreflexic bladder	Muscarinic receptor antagonists	Constipation, dry mouth, tachycardia
Sympathomimetics Norepinephrine Pseudoephedrine	Open bladder neck	α-Receptor antagonists	Arrhythmia, hypertension, coronary vasospasm, excitability, tremors
Antiadrenergics (alpha blockers) Phenoxybenzamine Phentolamine Terazosin Doxazosin Tamsulosin Alfuzosin	Smooth sphincter dyssynergia (competent, nonrelaxing bladder neck)	α-Receptor agonists	Orthostatic hypotension, dizziness, rhinitis, retrograde ejaculation
Tricyclic antidepressants Amitriptyline Imipramine	Hyperreflexic bladder with stress incontinence	Anticholinergic and sympathomimetic properties	Myocardial infarction, tachycardia, stroke, seizures, blood dyscrasias, dry mouth, drowsiness, constipation, blurred vision
Benzodiazepines Chlordiazepoxide	Extremity spasticity with detrusor-sphincter dyssynergia	γ-Aminobutyric acid (GABA) channel activator, centrally acting muscle relaxant	Dizziness, drowsiness, extrapyramidal effects, ataxia, agranulocytosis
Baclofen	Extremity spasticity with detrusor-sphincter dyssynergia	GABA _B channel activator (?); exact mechanism unknown; centrally acting muscle relaxant	Central nervous system depression, cardiovascular collapse, respiratory failure, seizures, dizziness, weakness, hypotonia, constipation, blurred vision*
Dantrolene	Extremity spasticity with detrusor-sphincter dyssynergia	Direct muscle relaxant by calcium sequestration in the sarcoplasmic reticulum	Hepatic dysfunction, seizures, pleural effusion, incoordination, dizziness, nausea, vomiting, abdominal pain
Botulinum toxin	Detrusor-sphincter dyssynergia	Inhibits release of acetylcholine	Repeated injections necessary

*Note that baclofen is also administered intrathecally by an implanted pump in these patients, and adverse effects are primarily limited to the central nervous system. Bladder contractility may also be reduced. No significant change occurs in detrusor-sphincter dyssynergia.

finger in the patient's anal canal. The bulbocavernosus reflex should be tested. Because deep tendon reflexes at the patella reflect status of the spinal cord at L3-L4, hyperreflexia at the knee almost certainly indicates increased tone at the pelvic diaphragm and thus detrusor-sphincter dyssynergia. Absence of the toe plantar flexors reflects either damage to S2 or a supraconal lesion, and it therefore predicts damage to the external urinary sphincter and possible involvement of the bladder. For patients with spinal cord injury, the return of deep reflexes below the level of injury heralds the recovery from spinal cord shock. The first and most important determination with regard to bladder function is the establishment of good bladder evacuation. The abdomen must therefore be examined for bladder palpability after a trial of voiding. Either a bladder ultrasound scan or urinary catheterization should be performed to determine the postvoid residual.

Functional Limitations

Functional limitations are typically due to incontinence and include social rejection and isolation. Incontinence may also affect a patient's ability to work, to participate in recreational activities, and to sustain interpersonal relationships.

Diagnostic Studies

All patients with neural injury should have blood chemistries at baseline and periodically during follow-up for blood urea nitrogen and creatinine concentrations. Renal and bladder ultrasound examination should be performed to assess the status of the urinary tract: size, shape, and echogenicity of the kidneys; presence of hydronephrosis or hydroureter; presence of renal or bladder stones; change in hydronephrosis during and after voiding; and completeness of the void.

If vesicoureteral reflux or urethral strictures are suspected, voiding cystourethrography may be performed.

If renal stones are suspected, non-contrast-enhanced computed tomography (renal stone protocol) is an excellent tool for identification of the size and location of the stones. In dealing with renal stones, it is sometimes important to assess calyceal or ureteral anatomy or differential renal function, in which case intravenous urography may be performed. Finer qualitative assessment of differential renal function may be performed by technetium Tc 99m mertiatide ($^{99m}\text{Tc-MAG3}$) nuclear renal scan. When compromise of renal function is suspected, this test may be useful.

Transrectal linear array ultrasonography may be performed to assess prostate size, prominent median prostatic lobe, ledge at the bladder neck [16], or proximal urethral and bladder neck strictures. Voiding videofluoroscopy or ultrasonography can show abrupt cessation of urine flow.

Cystoscopy is an excellent tool for studying bladder and urethral anatomy; it quickly identifies the presence of a urethral stricture (although it may not determine its length or depth), provides an assessment of internal prostatic size, provides indirect evidence of high intravesical pressures (bladder trabeculation), and readily demonstrates bladder stones. Cystoscopy is essential in the assessment of hematuria (more than five red blood cells per high-power field on two or more urine specimens). Whereas hematuria in neurally injured patients is commonly related to infection or traumatic catheterization, the use of indwelling catheters for a long time places these patients at a significantly higher risk for bladder cancer [17]. It has been suggested, therefore, that these patients undergo surveillance cystoscopy

annually, particularly if they have other risk factors for bladder cancer, such as smoking or a family history with bladder cancer. After bladder irrigation with normal saline, a urine specimen for malignant cell cytology may be helpful as a screening test. No test is as sensitive for the detection of bladder tumors as the cystoscopic examination and biopsy of a suspicious area.

Note that cystoscopy does not provide functional information. The best single test for bladder function is urodynamic testing. Formal urodynamic testing, including cystometrography and electromyography, is crucial to the proper documentation of bladder and outlet function. The test is subject to inherent errors in technique, interpretation, and cooperation of the patient; however, the astute clinician must interpret the results in light of the entire clinical scenario. Properly performed, it will elucidate and quantify postvoid residual of urine, bladder capacity, bladder compliance, bladder pressures during filling and voiding, and external sphincteric coordination. In conjunction with videofluoroscopic monitoring, ureteral reflux, bladder position, and internal and external sphincteric function may be visualized. Urodynamics should be performed at baseline for all patients with neurologic disease. Because of central nervous system shock in the acute phase of injury, it is best to perform urodynamics after the shock resolves—on return of distal reflexes. Figure 137.2 illustrates a normal voiding pattern. Figure 137.3 illustrates the urodynamic findings of an areflexic bladder. Figure 137.4A, B shows detrusor-sphincter dyssynergia. The sonographic correlate of detrusor-sphincter dyssynergia is shown in Figure 137.4C (nonrelaxation of the external urethral sphincter is demonstrated).

FIGURE 137.2 Urodynamic study consisting of simultaneous cystometrography (CMG), rectal pressure, and electromyography (EMG) of the external urethral sphincter. During bladder filling, the desire to void is usually expressed between 300 and 400 mL. When the normal person is asked to hold urine, the external urethral sphincter contracts and the bladder relaxes. When asked, this person voided voluntarily at a filling volume of approximately 350 mL; the external urethral sphincter relaxed just before voiding, indicating a normal study.

FIGURE 137.3 Urodynamic study demonstrating an areflexic bladder in a patient with spinal cord injury. There is minimal increase in electromyographic (EMG) activity during filling of the bladder. There is no bladder contraction, even after suprapubic (SP) tapping, indicating overdistention areflexia or a lower motor neuron lesion. CMG, cystometrography; RP, rectal pressure.

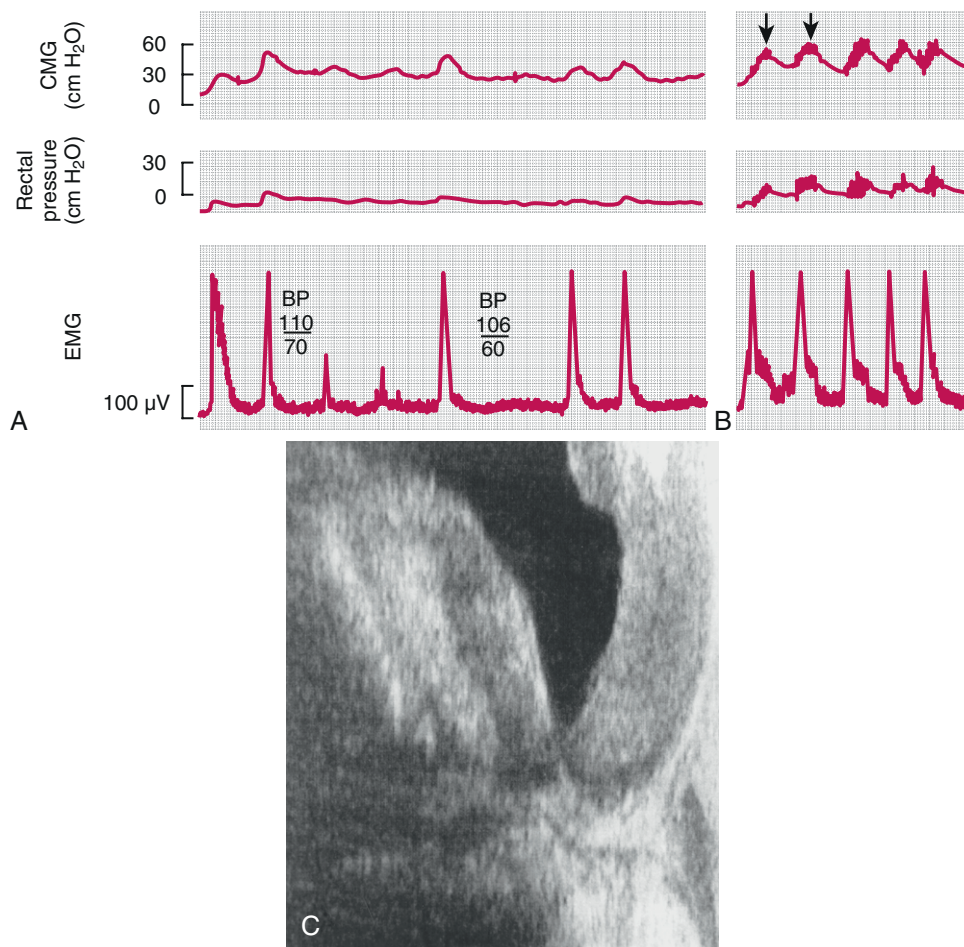

FIGURE 137.4 A and B, Detrusor-sphincter dyssynergia in a patient with spinal cord injury; each bladder contraction on the cystometrograph (CMG) is accompanied by a marked increase in electromyographic (EMG) activity of the external urethral sphincter. BP, blood pressure. C, Ultrasound cystourethrogram during an attempted void in a patient with spinal cord injury with detrusor-sphincter dyssynergia. The passage of urine is abruptly stopped by closure of the external urethral sphincter, and the posterior urethra is dilated.

Differential Diagnosis

The diseases listed in [Table 137.1](#) are the most common causes of neurogenic bladder.

Treatment

Initial

The priorities of bladder management relate first to preservation of renal function and abolition of infection and second to social concerns. Overflow incontinence, ureteral reflux, or high bladder pressures in the presence of renal insufficiency or active infection must be managed aggressively by ensuring proper egress for urine. A source for persistent infection, such as urinary lithiasis, must be sought and, if found, eliminated. High bladder pressure, particularly if it is sustained (>40 cm H_2O), ultimately results in deterioration of renal function and should therefore be addressed actively, even if renal function is normal [18].

Rehabilitation

Patients at risk for degenerative neurogenic bladders, particularly those with (or at risk for) sensory neuropathies (e.g., diabetic patients, phenytoin users), should have a timed voiding schedule to prevent overdistention and progression to bladder areflexia. A 24-hour voiding diary, including fluid intake, time and quantity voided, and postvoid residual (by catheterization or ultrasound evaluation), should be recorded periodically. These patients should void every 6 hours, void again immediately after the first void, and adjust their fluid intake and voiding frequency according to the voiding diary. Patients with diabetes should be careful to maintain good glycemic control, not only for global prevention of related degenerative disease but also to prevent osmotic diuresis.

Most neurogenic bladder lesions are associated with impaired bowel function. Fecal impaction and obstructed constipation may also cause mechanical obstruction to the passage of urine. Further, many of the medications used to reduce bladder contractility, particularly the anticholinergics, exacerbate bowel motility dysfunction. It is therefore important that these patients be routinely prescribed high-fiber diets, stool softeners (e.g., docusate, 100 mg orally, three times daily), laxatives (e.g., psyllium, 1 packet [3.4 g] orally every day), and suppositories (e.g., bisacodyl, 10 mg per rectum every day) and undergo digital stimulation either daily or every other day. Digital stimulation is best performed after either a meal or coffee or tea to take advantage of the gastrocolic reflex.

The Credé method (suprapubic pressure) alone can lead to high intravesical pressures and even vesicoureteral reflux. Such pressure, or persistent tapping of the suprapubic region for 2 minutes at a time, should be performed only when methods to relieve bladder outlet obstruction have been ensured. This should not be performed in patients with active detrusor-sphincter dyssynergia and detrusor hyperreflexia because it will only exacerbate already high bladder pressures, and urine will not be completely evacuated.

Acute Phase and Central Nervous System Shock Phase

This phase usually lasts days to weeks. The bladder is areflexic during this period, and adequate bladder drainage should be secured to prevent the areflexic bladder from developing overdistention and myogenic failure. Indwelling continuous Foley catheterization (14F) is the easiest way to ensure bladder drainage. Alternatively, intermittent catheterization may be performed (after the initial phase of diuresis) and, when it is used from the onset, reduces the incidence of infection and stone disease [19].

Patients do need training or assistance in self-catheterization. Rehabilitation nurses may also be involved in this educational process. Catheterization is performed every 4 to 6 hours and fluid is restricted to a maximum of 2 liters per day, if possible. The frequency of catheterization should be adjusted so that residuals are no more than 300 to 400 mL. For patients with a hyperreflexic bladder, long-term intermittent catheterization requires mitigation of the detrusor reflex with anticholinergics ([Table 137.2](#)).

Anticholinergic Drugs (Drugs to Increase Bladder Capacity)

In the human being, bladder (detrusor muscle) has muscarinic receptors (M_2 and M_3 receptors). M_3 receptors compared with M_2 receptors are small in number but are mainly responsible for bladder contraction. The antimuscarinic drugs oxybutynin, tolterodine, darifenacin, solifenacin, and trospium are the five major drugs ([Table 137.3](#)) currently available to modulate detrusor hyperreflexia, to increase bladder capacity, and to reduce bladder voiding pressures. Comparative clinical studies have shown that oxybutynin and solifenacin may be marginally more effective than tolterodine, although tolterodine seems to be better tolerated; but dry mouth and constipation are still major problems for compliance of patients with all of them because of the widespread existence of M_3 receptors, particularly in the salivary glands. Except for trospium chloride, most of the other drugs shown in [Table 137.3](#) are tertiary amines and cross the blood-brain barrier, enhancing the anticholinergic factor. There is evidence that they may lead to some loss of memory, particularly in elderly patients [20].

Anticholinergic drugs have been, on the whole, a disappointment in the treatment of incontinence associated with neurogenic detrusor overactivity. Whereas urodynamic parameters often improve and the number of incontinence episodes is often reduced by anticholinergics, incontinence often remains a problem. Mirabegron (Myrbetriq; Astellas Pharma US, Inc), a selective β_3 -receptor agonist that causes detrusor fundus relaxation, has emerged recently as a pharmaceutical alternative for patients failing to respond to anticholinergic therapy in the able-bodied idiopathic overactive bladder population [21]. It has not yet been studied in the neurogenic bladder population, although a trial is certain for this in the near future. According to the Food and Drug Administration, its most important side effect is significant hypertension, noted in 11.3% (compared with 7.6% in the placebo arm), which is reversible with discontinuation of the drug. It is dosed at 25 mg or 50 mg orally once daily. Botox injections are used in the bladder wall to reduce bladder

Table 137.3 Summary of Anticholinergic Agents

Anticholinergic*	T _{1/2} (h)	Typical Side Effects	Comments
Oxybutynin Ditropan	2-3	Dry mouth, constipation, blurry vision, headaches Elderly: cognitive impairment, hallucinations	Typical dose is 5 mg orally tid
Ditropan XL	13	Same as oral oxybutynin	Slower absorption with more stable blood concentration Typical dose is 10 mg orally daily, but doses up to 40 mg daily are generally safe
Oxytrol (oxybutynin patch)	2-5	Same as oral oxybutynin, plus local skin irritation	Bypasses first pass of the liver, which reduces the concentrations of active metabolites that are thought to contribute to side effects Dosed at 3.9 mg/day, 1 patch 2 times/week, alternating skin sites
Tolterodine Detrol	2-10	Same as oral oxybutynin	Possibly more selective to urinary M receptors, resulting in fewer side effects Typical dose is 2 mg orally bid
Detrol LA	2-10	Same as oral oxybutynin	Slower absorption with more stable blood concentration Typical dose is 4 mg orally daily
Darifenacin (Enablex) Tropium	13-19 20	Same as oral oxybutynin Same as oral oxybutynin	Typical dose is 7.5 mg or 15 mg orally daily Quaternary amine does not cross the blood-brain barrier well, resulting in minimal central nervous system anticholinergic effect, and it may limit cognitive side effects (particularly in the elderly)
Sanctura XR	36	Same as oral oxybutynin	Typical dose is 20 mg orally bid More stable blood concentration
Solifenacin (VESIcare)	45-68	Same as oral oxybutynin	Typical dose is 60 mg orally daily Typical dose is 5 mg or 10 mg orally daily

*Unless patients with urinary retention are managed with a catheter, anticholinergic therapy is contraindicated for them. Anticholinergics are also contraindicated in patients with gastric retention and patients with uncontrolled narrow-angle glaucoma.

T_{1/2} (h), pharmacokinetic half-life (hours).

pressures to safe levels (<40 cm H₂O) and to achieve continence between catheterizations.

Procedures

Another alternative to long-term management of bladder drainage is placement of a suprapubic catheter. This is preferable to chronic transurethral catheterization because it eliminates the risk of urethral or meatal erosion and is less often the cause of epididymitis or orchitis. Urinary tract infections, however, are just as likely, and these catheters require changing once a month. They are best placed either in the operating room under cystoscopic guidance or, better, through suprapubic incision to ascertain that the catheter ultimately resides as superiorly as possible, far from the bladder neck. This helps prevent irritation at the bladder neck, which often causes reflex bladder contractions, particularly if the catheter balloon (also in an indwelling Foley catheter) drops down into the posterior urethra (Fig. 137.5).

Botulinum Toxin

Patients with neurogenic overactive bladder failing to respond to anticholinergic therapy may benefit from periodic administration of intravesical onabotulinumtoxinA, the leading manufactured agent being Botox. Its purported mechanism of action is the inhibition of release of acetylcholine at the presynaptic cholinergic junction [22], which effectively suppresses detrusor contraction [23]. Botox is typically administered by submucosal injection cystoscopically in

0.5-mL aliquots; the total dose ranges from 100 to 300 units through a rigid or flexible cystoscope.

Prospective randomized double-blind placebo-controlled trials showed that Botox is efficacious and safe in patients with neurogenic detrusor overactivity and incontinence, with clinical benefits seen up to 9 months after injection [24,25]. Botox reduced incontinence episodes and improved quality of life in patients with multiple sclerosis and in patients with spinal cord injury (T1 or lower). Median time to a request for re-treatment was 42 weeks [24]. In a 7-year retrospective review of 216 patients given Botox or Dysport in 365 sessions, significant improvement was seen in maximum detrusor pressure, detrusor compliance, and bladder capacity at 6 weeks and 6 months; a quarter of the patients never stopped anticholinergic therapy; half discontinued after 6 weeks; and after 6 months, 35% still had not resumed anticholinergic therapy [26]. In a randomized placebo-controlled study [27], similar improvement was demonstrated in urodynamic outcomes. Reitz and colleagues [28] showed that 73% of neurogenic detrusor overactivity incontinent patients achieved continence with Botox at 12 weeks.

After Botox injection, postvoid residuals may be significantly elevated in a dose-dependent fashion; a third of patients had urinary retention and required intermittent catheterization [24]. Another drawback of this agent is need for repeated treatment periodically. Rarely, generalized weakness, difficulty in swallowing, or dysarthria ensues, although these side effects reverse spontaneously in several weeks [26].

FIGURE 137-5 A, Linear array ultrasound–voiding cystourethrogram shows a contracted bladder neck and dilated prostatic urethra. B, The balloon of the urethral Foley catheter is lodged in the prostatic urethra. This occurs uncommonly; however, it may lead to inadequate bladder drainage and, in patients with lesions above T6, autonomic dysreflexia.

Sacral Nerve Stimulation

For patients with hyperreflexic bladders, electrical stimulation through peripheral patch electrodes or implantation of a sacral nerve root stimulator may be of some benefit [29–31]. The treatment is dependent on an intact sacral reflex and works by modulation of signaling from somatic and afferent nerves involved in the micturition reflex pathway. Patients must be able to empty the bladder voluntarily (or by Valsalva maneuver) when the device is turned off or be capable of performing intermittent self-catheterization.

Installation of a sacral nerve stimulator may be done in two stages: a test phase with temporary wires, typically lasting about 1 week; and pending a successful outcome with the test phase, installation of a permanent system. Correct placement of the lead is done under local anesthesia with the patient awake and conversant in the prone position. Its placement in the correct foramen level (typically S3) and depth of penetration to the anterior nerve root are confirmed by real-time fluoroscopic imaging, assessment for a tapping sensation in the vagina or perineum, dorsiflexion of the ipsilateral great toe, and bellowing contraction of the perineal area. For those having a permanent implant, the patient is then typically sedated for subcutaneous placement of the implantable pulse generator and tunneling of the wire.

The studies reported are primarily in able-bodied populations with idiopathic detrusor hyperreflexia. Limited evaluation thus far in the neurogenic population, however, has shown promise. In a review and meta-analysis of 26 studies, including 357 patients, and a mean follow-up of 26 months concerning the safety and efficacy of sacral nerve stimulation in neurogenic lower urinary tract dysfunction, the pooled success rate was 68% for the test phase and 92% for permanent sacral nerve stimulator implantation [32]. Adverse events were seen in none in the test placement group and 24% in the permanent placement group. Adverse effects include pain, infection, and lead migration. In one study, 33% required surgical revision [33]. The life span of these implantable pulse generators varies with intensity of use but averages about 5 years.

Sacral nerve stimulator implantation is relatively contraindicated in multiple sclerosis patients to the extent that

these patients are frequently studied by magnetic resonance imaging over time. It is also not appropriate for patients with significant spinal and sacral bone abnormalities.

Surgery

Transurethral sphincterotomy has been used in suprasacral lesions in the past and has fallen into disfavor because of intraoperative and delayed bleeding potential. Use of a laser in a contact mode causes virtually no intraoperative bleeding [11,34]. This procedure results in incontinence postoperatively and requires the use of an external condom catheter.

There are rare circumstances in which bladder management has aggravated renal function, evidenced by recurrent ascending urinary tract infections or a bladder that is too contracted to store sufficient volumes. Some patients find it socially unacceptable to be incontinent and are willing to perform intermittent self-catheterization, but the body habitus precludes them from this. In such cases, there are certain reconstructive options that should be considered. An incontinent urinary diversion with a stoma in abdomen that drains urine in a bag may be performed [35,36]. Cystectomy may be combined with this procedure or the bladder may be left in situ with a small risk of pyocystis.

In patients willing and able to perform intermittent self-catheterization, the most common reconstructive alternative is an augmentation cystoplasty. The bladder is augmented by a segment of ileum, and the ureters remain in their native locations. Bladder pressure is reduced and capacity increased, thus protecting the upper tracts from side effects of high pressure bladder. The drainage of urine is performed by intermittent self-catheterization. This procedure may be combined with an artificial urinary sphincter in patients with incompetent sphincter.

For bladders that have low pressures and good compliance but leak through fixed sphincters, the Mitrofanoff and bladder neck closure may be an excellent option. Spina bifida patients with conus lesions might be good candidates for this procedure. Egress through the bladder neck is eliminated, and the appendix is interposed between the

bladder and the umbilicus where it is opened. In the common event that the bladder has poor compliance, an ileal bladder augmentation will raise bladder volume and lower bladder pressure. Patients would then catheterize their augmented bladders through the umbilicus.

Potential Disease Complications

Urinary tract infections, kidney stones, and autonomic dysreflexia are common disease complications associated with neurogenic bladder. Social isolation due to incontinence may lead to depression.

Patients with spinal cord injury who have a urinary tract infection commonly may not present with symptoms [4]. Fevers, chills, back pain, suprapubic pain, dysuria, frequency, and testicular swelling in the setting of positive urine cultures should be regarded as a urinary tract infection. Patients without overt symptoms of pyelonephritis, prostatitis, epididymitis-orchitis, or cystitis are more difficult to diagnose, particularly if they have an indwelling catheter or are being managed by intermittent catheterization. Those using catheters are virtually always colonized with bacteria, and the injudicious use of antibiotics will only select out resistant strains. Factors indicating a need for treatment include urinary lithiasis, as this is most often related to infection (struvite, magnesium ammonium phosphate), and pyuria (8 to 10 white blood cells per high-power field, or 100 white blood cells per milliliter) in the setting of bacteriuria (more than 10,000 colony-forming units per milliliter). Urine pH should be checked periodically; pH above 7 is invariably associated with infection from urea-splitting organisms, which may lead to struvite stone formation.

Patients with detrusor-sphincter dyssynergia or urinary retention of any kind should have the bladder drained expeditiously with a fresh Foley catheter during the course of their treatment to ascertain good egress of infected urine. If prostatitis is suspected, transurethral insertion of a Foley catheter is relatively contraindicated, and drainage should be ensured suprapubically. Fluoroquinolones are an excellent first choice for most urinary tract infections; therapy may then be tailored to culture and sensitivity results. Three to 5 days is sufficient for cystitis. Pyelonephritis requires 2 weeks of therapy. Epididymitis requires at least 3 weeks of therapy, and prostatitis often requires 6 weeks. A higher incidence of bladder cancer (squamous cell) has been reported in patients with long-term indwelling bladder drainage [37].

Autonomic Dysreflexia

The control of widespread sympathetic activity below the spinal lesion is the key factor in the management of autonomic dysreflexia, and prevention is the first concern. Noxious stimuli, such as overdistention of the bladder, should be reversed immediately by catheter drainage. Local instillation of 20 mL of lidocaine jelly of 0.3% tetracaine through the Foley catheter or suprapubic tube may provide topical anesthesia of the vesical mucosa and reduce triggering impulses to the spinal cord. Consideration of procedures for patients at risk (spinal lesions above T6) should include spinal anesthesia, use of ganglion blockers, and use of adrenergic blockers.

In the acute episode, if reversal of the noxious stimulus fails to control symptoms, administration of nifedipine (10-30 mg sublingually [38]) or nitropaste (about 1 inch applied on the body surface) is usually adequate to reduce blood pressure. Note that normal blood pressure for a patient with spinal cord injury is less than 100 mm Hg systolic. If nifedipine fails, hydralazine (10 to 20 mg intravenously or 10 to 50 mg intramuscularly) may be administered. Use lower doses initially and repeat every 20 to 30 minutes as necessary to maintain a low blood pressure. Other useful drugs include alpha blockers (such as prazosin, terazosin, guanethidine, and clonidine) and anticholinergics (such as oxybutynin and tolterodine). For long-term management of autonomic dysreflexia, clonidine (0.1 to 0.3 mg orally twice daily) is useful. Note that the chronic form of this syndrome is often related to active detrusor-sphincter dyssynergia, and methods aimed at control of this phenomenon, such as transurethral sphincterotomy, may alleviate the patient of autonomic dysreflexia [11].

Potential Treatment Complications

For those who have had indwelling Foley catheters for an extended period (more than several days) and require catheter removal or exchange, antibiotics should be administered prophylactically before, during, and after removal of the existing catheter. Gentamicin (80 mg intramuscularly once just before removal of the catheter) is appropriate for most patients with stable renal function, even if function is impaired, and has both gram-positive and gram-negative coverage. Those with prosthetics, aortic stenosis, or other risk factors for seeding should have coadministration of ampicillin (1 g intravenously) for enterococcus coverage. Alternatively, amoxicillin-clavulanic acid (750 mg) or ciprofloxacin (500 mg) may be given orally twice daily before and 24 hours after placement of the new catheter. In addition, the bladder should be irrigated gently through the catheter with 50 mL of Neosporin G.U. irrigant (DSM Pharmaceutical, Inc., Greenville, North Carolina) (at body temperature) containing 40 mg/L Neomycin and 200,000 units/L Polymixin B. Irrigation should be avoided in patients with a defect/ulceration in the bladder mucosa or in postoperative patients for the toxic absorption of these drugs; ideally, a new catheter is placed and urine for culture is obtained to avoid culturing bacteria in the biolayer around the catheter [32]. Bladder is irrigated with GU irrigant every 4 hours for at least 48 hours. Irrigation is continued while the catheter is being pulled through the urethra to remove urethral pathogens. This method has been shown to significantly reduce urinary tract infection related to catheter changes [33, 34].

Attention to hygiene is paramount in the prevention of urinary tract infections in the spinal cord-injured population. Those on condom catheter drainage should change it once a day. Leg bags should be routinely disinfected with 6% Clorox solution or bleach (most cost-efficient) and then washed well with running water. Wheelchair seat cushions should be changed and cleaned, and the patient should take a shower daily to reduce colony counts at the perineum. Suppressive treatment should be considered for patients who demonstrate recurrent infections. Nitrofurantoin, 100 mg orally daily, is sufficient. Methenamine hippurate

(1g orally twice a day) and ascorbic acid (500mg orally daily) acidify the urine and may be good for prophylaxis of urinary tract infection [40,41].

Stoma care after colostomy is a source of great consternation for many who have it because of frequent appliance leaks and skin irritation. Also, the stoma must be situated properly on the abdomen according to the patient's habitus and positioning in the wheelchair. Bladder augmentations of any kind are susceptible to perforations and life-threatening infections (as much as 10%). These patients have a 3% chance of small bowel obstruction from adhesions during their lifetime. Chronic indwelling Foley catheters carry the potential for urinary infection, meatal erosion, epididymitis-orchitis, stone disease, and urethral fistula. In women, the urethra becomes patulous in time and incontinence ensues with or without a catheter. Finally, with time and repeated infections, indwelling catheters put patients at risk for development of squamous cell cancer of the bladder [37]. Although the incidence is low, gross hematuria should be evaluated with great suspicion in these patients because this disease is often advanced at the time of discovery and is often fatal [39].

Definition

Within the nervous system, there are peripheral, somatic, and autonomic (sympathetic and parasympathetic) contributions to the various organ-based functions. Related to the gastrointestinal system, several end-organ problems resulting from neurologic dysfunction include prolonged colonic transit time, reduced anorectal sensibility, and lack of voluntary control of the external anal and urethral sphincters, often associated with a dyssynergic response. The severity of colorectal dysfunction depends on the degree of completeness and level of the spinal cord injury [1,2]. However, specific evaluation is required in individual cases. These problems have an extensive impact on quality of life. Our study based on interviews of 125 consecutive male patients and 2 female patients with spinal cord injury showed that 27% of patients had chronic disabling gastrointestinal problems requiring alteration of their lifestyle; symptoms usually appeared 5 to 10 years after injury ($P < .05$) [3]. Severity of bowel dysfunction correlated with high level of lesion, completeness of cord injury, and longer duration of injury (≥ 10 years) [4,5].

Bowel Innervations and Gastrointestinal Motility

Unlike in the bladder, small and large bowel movements are mainly autonomous and may be influenced with some spinal cord lesions. The vagus nerve, which arises intracranially and

provides parasympathetic innervations from the esophagus to the splenic flexure of the colon, is spared in spinal cord lesions (Fig. 138.1). The pelvic nerve carries parasympathetic fibers from S2-S4 to the descending colon and rectum. Some pelvic nerve branches travel proximally and innervate the transverse and ascending colon [6]. Sympathetic innervations are supplied by the superior and inferior mesenteric (T9-T12) and hypogastric (T12-L2) nerves. The somatic pudendal nerve (S2-S4) innervates the pelvic floor.

The intrinsic nervous system of the gastrointestinal tract, which includes Auerbach plexus, is situated in the colonic wall between the longitudinal and circular muscle layers. This nerve supply helps coordinate colonic wall movement and the advancement of stool through the colon. The behavior of the bowel can be controlled by the intrinsic innervations of the gut independently of input from the central nervous system.

The extrinsic nervous system also innervates the colon and includes the parasympathetic, sympathetic, and somatic nerves [4,5]. Peristaltic waves travel both toward and away from the ileocecal valve in the ascending colon; but in the descending colon, the waves travel mainly to push the contents to the anus [4]. The motility of the colon is performed by three primary mechanisms: myogenic, chemical, and neurogenic. The myogenic transmission of signals occurs between enteric smooth muscle cells that are interconnected by gap junctions, which produces transmission from cell to cell. Most intestinal muscle displays autorhythmicity that causes colonic wall contractions [4].

Chemical control is through the activity of neurotransmitters and hormones. The chemicals influence the promotion or inhibition of contractions through the action of the central nervous system or autonomic nervous system or by direct action on muscle cells. This activity can be triggered by luminal stimuli that are detected by nerves through epithelial intermediation. Epithelial enterochromaffin cells act as sensory transducers that activate the mucosal processes of both intrinsic and extrinsic primary afferent neurons through their release of 5-hydroxytryptamine (5-HT). Intrinsic primary afferent neurons are present in both the submucosal and myenteric plexuses. Peristaltic and secretory reflexes are initiated by submucosal intrinsic primary afferent neurons, which are stimulated by 5-HT acting at 5-HT_{1P} receptors. Serotonergic transmission within the enteric nervous system and the activation of myenteric intrinsic primary afferent neurons are 5-HT₃ mediated [6]. Signaling to the central nervous system is also predominantly 5-HT₃

FIGURE 138-1 Important central neural control of the pelvic organs and resultant dysfunctions after denervation. (Modified with permission from Zafar Khan.)

mediated. The gut is thus the only organ that can display reflexes and integrate neuronal activity even when it is isolated from the central nervous system.

The neurogenic mechanism of colonic control is through the enteric nervous system, which coordinates all segmental motility and some propagated movement. The number of intrinsic neurons in the gut greatly exceeds the number of fibers in the vagus and splanchnic nerves. In humans, the enteric nervous system contains up to 100 million neurons, compared with only 2000 efferent fibers in the vagus nerve, suggesting that intrinsic nerves may direct most reflex and control activities and that the extrinsic innervations may serve only a modulatory function [7,8].

Normal defecation is the result of a complex interaction between muscles, nerves, and central nervous system. For a normal defecation, there needs to be a mass movement of colonic contents associated with relaxation of internal and external anal sphincters. Mass movement of colonic contents before defecation associated with internal sphincter relaxation has recently been shown to result from high-amplitude propagating contractions in children even with sigmoid dysmotility [9]. The colon absorbs fluids, electrolytes, and short-chain fatty acids; provides for growth of symbiotic bacteria; secretes mucus for lubrication of feces; and slowly propels stool toward the anus [10]. The contents in the distal colon are retained until bowel evacuation. Transport of contents may take 12 to 30 hours from the ileocecal valve to the rectum [2].

Neurogenic Bowel

A neurogenic bowel occurs when there is a dysfunction of the colon or rectosigmoid due to the lack of nervous control

[11–13]. The enteric nervous system remains intact after spinal cord injury. However, depending on the level of the injury, different bowel problems and complications may arise. The lower motor neuron bowel syndrome or areflexic bowel results from a lesion affecting the parasympathetic cell bodies in the conus medullaris, cauda equina lesions, or damage to the pelvic nerves. No spinal cord-mediated peristalsis occurs, and there is slow stool propulsion. Only the myenteric plexus coordinates segmental colonic peristalsis, and a dryer, rounder stool shape occurs. Because of the denervated external anal sphincter, there is increased risk for incontinence. The levator ani muscles lack tone, and this reduces the rectal angle and causes the lumen of the rectum to open. The lower motor neuron bowel syndrome produces constipation and a significant risk of incontinence due to the lax external anal sphincter. A lesion above the conus medullaris causes an upper motor neuron bladder and bowel syndrome or hyperreflexic bladder and bowel. There is increased colonic wall and anal tone. The voluntary control of the external anal sphincter is lacking, and the sphincter remains tight, thereby retaining stool. The nerve connections between the spinal cord and the colon, however, remain intact; therefore, there is reflex coordination and stool propulsion. The upper motor neuron bowel syndrome with supraconal lesions in the spinal cord produces constipation and fecal retention at least in part owing to the hyperactivity of the external anal sphincter.

Pathophysiology of Constipation in Neurologically Impaired Patients

In neuropathic bowel, constipation is usually a major consequence [11–13]. The pathophysiologic mechanisms of

constipation are obstructed defecation, weak abdominal muscles, impaired rectal sensation, and delayed colonic transit time. Both incomplete and complete lesions can have an obstructed defecation or fecal incontinence [14]. The mechanism for fecal incontinence is due to areflexic or atonic anal sphincter, uninhibited rectal contractions, poor rectal sensibility, and lack of anal sphincter tone and contraction (conus and cauda equina lesions).

During attempts to defecate, in some able-bodied persons with chronic constipation, there is also an inappropriate contraction (or failed relaxation) of the puborectalis and of the external anal sphincter muscles. This paradoxical contraction of the pelvic floor musculature during straining at defecation is also called pelvic floor dysfunction [14,15] or pelvic floor dyssynergic response. This is not a true dyssynergia because it can be relaxed with volitional control. The diagnostic criteria were elucidated in the Rome II report and include those for functional constipation plus at least two of three investigations among manometry, electromyography, and defecography showing inappropriate contraction of or failure to relax the pelvic floor muscles [14,15]. Patients can learn to relax the pelvic floor musculature with biofeedback to manage functional obstructed defecation. This dyssynergic response, therefore, needs to be distinguished from true detrusor anal sphincter dyssynergia due to neurologic impairment, in which biofeedback may not have any role for the functional improvement.

Symptoms

There is a high prevalence and wide spectrum of gastrointestinal symptoms after spinal cord injury. Abdominal bloating and constipation are usually related to specific spinal cord levels of injury [16]. The limited manner through which spinal cord-injured patients can manifest symptoms resulted in complaints that were characteristically vague [3]. The most common problems that impaired quality of life were poorly localized abdominal pain (14%) and difficulty with bowel evacuation (20%), hemorrhoids (74%), abdominal distention (43%), and autonomic dysreflexia. Twenty-three percent of our population required at least one admission to the hospital for a gastrointestinal complaint after their injury. The prevalence of chronic gastrointestinal symptoms increased with time after injury [3].

Physical Examination

For the rehabilitation of neurogenic bowel, an individual evaluation [17,18] is important with a careful rectal examination and anorectal neurologic testing to document degree of neurologic impairment. A neurologic examination can reveal the extent of the nerve damage and the completeness of the spinal cord injury. The abdomen should be inspected and palpated for distention, palpable fecal masses, increased abdominal muscle tone indicative of spasticity, and bowel sounds. The rectal examination can provide information about external anal sphincter tone, stool in the rectal vault, presence of hemorrhoids, cystocele in women, or masses, and it assesses the tone and ability to produce voluntary contraction of the puborectalis muscles.

The bulbocavernosus reflex assesses the integrity of the local spinal reflex arc; its absence along with poor anal tone

indicates a conus or cauda equina lesion (lower motor neuron). It is also important to assess the patient's strength in the upper and lower extremities, hand function, sitting balance, and ability to transfer; the length of the patient's arms, legs, and trunk; and the patient's weight. These factors are helpful to determine whether the patient can perform his or her own bowel program or whether assistance will be needed. Berkowitz and colleagues [19] found that 37% of all patients with spinal cord injury need assistance with bowel care. People with tetraplegia are more likely to need assistance than are people with paraplegia.

Functional Limitations

There is some degree of loss of voluntary control for bowel evacuation, constipation, unpredicted incontinence, abdominal distention, and associated discomfort, depending on the degree and level of completeness of the neurologic lesion.

Diagnostic Studies

Colonic and anorectal dysfunctions are recognized as the principal pathophysiologic mechanism underpinning chronic constipation and particularly obstructed constipation in neurologically impaired patients [20].

Colonic motor activity comprises four main components: myoelectric activity [21], phasic contractile activity, tonic contractile activity, and intraluminal transit. Specific methods are available for the assessment of each separate component, but no single investigation gives information about all four types of activity. In current clinical practice, evaluation of colonic motor function is almost exclusively limited to assessment of intraluminal pressure and transit time [22,23]. Although the direct assessment of colonic contractile activity can be achieved through colonic manometry, this procedure is only slowly gaining clinical acceptance, notably in pediatrics. Other novel methods are also available; two techniques exist for the routine assessment of colonic (or whole gut) transit, both of which involve irradiation of the subjects: radiopaque markers [24] and radionuclide scintigraphy [25]. Wireless (telemetric) motility capsules [26] with magnetic markers to obviate irradiation are currently being tried, but they need further validation before being incorporated into general clinical practice. Together with assessment of rectal evacuation and rectal sensation, studies of colonic transit should form the cornerstone of investigation of chronic idiopathic constipation in patients with functional or partial neurologic impairment. These investigations have led to the conceptualization of constipation in three broad and overlapping categories: normal-transit constipation, slow-transit constipation, and evacuation disorders.

Anorectal Dyssynergia

For the precise diagnosis of anorectal dyssynergia, particularly in incomplete or functional lesions, anorectal manometry along with simultaneous electromyography of the external anal sphincter is important to distinguish between functional constipation [15,16] and obstructed constipation due to a neurologic lesion. It is also important to evaluate impairment due to an incomplete lesion (e.g., multiple sclerosis, pudendal nerve lesion after childbirth, lumbar disc disease,

back injury, or spinal tumor). Defecography, nerve stimulation and pudendal latency, ultrasonography, and magnetic resonance imaging may also be required for better understanding of gastrointestinal dysfunction. A rectal examination should be performed to look for a rectocele, voluntary anal contraction, and bulbocavernosus reflex to evaluate sacral nerve root lesions. Defecography detects structural abnormalities and assesses functional information on the movement of the pelvic floor and the organs that it supports; conversely, excessive descent (descending perineum syndrome) can also be a pathophysiologic mechanism of constipation. Defecography can also help complement anorectal manometry studies in ruling out slow transit and other causes of constipation. Magnetic resonance imaging or pelvic floor sonography can further complement the studies. This will help reduce morbidity rates and will improve the quality of life for the neurologically impaired patient.

Treatment

Initial

Unless there is an associated acute abdomen, the small bowel and the bulk of the colon are functional and are not paralyzed. Management of bowel evacuation will also depend on level of injury. In cauda equina lesions and also during the shock phase after spinal cord injury, there is a flaccid bowel; the management generally involves manual removal (disimpaction) of stool and use of a suppository. Digital stimulation may also be helpful with intact bulbocavernosus reflex. In patients with a supraconal lesion with spastic bowel, routine use of stool softeners, suppository insertion, and digital stimulation help evacuation of the fecal matter. Digital stimulation with and without suppository for about 20 to 30 minutes usually evokes bowel evacuation. Glycerin or Microlax suppository has been commonly used.

Rehabilitation

Bowel Management after Spinal Cord Injury

In the rehabilitation of the spinal cord-injured patient, adequate bowel evacuation in less than 60 minutes is an ideal goal; however, a large number of patients may require up to 180 minutes. It is therefore important to individualize the bowel program for adequate evacuation on the basis of the neurologic and physical status with a set time, diet control, and digital stimulation with or without a glycerin suppository [11]. Additional help to regulate the bowel with bulking agents by increasing water content (e.g., Metamucil) or stool softeners by increasing water penetration of stool (e.g., Coloxyl) has been useful in children. Iso-osmotic laxative (e.g., Movicol) and osmotic laxative (e.g., lactulose) are also widely used to help individualize the bowel program.

The addition of bisacodyl to aid myoelectric propagation activity, transit in the ascending colon, and rectal tone in humans has been reported. Internal anal sphincter relaxation associated with bisacodyl-induced colonic high-amplitude propagating contractions in children with constipation has also been reported: a coloanal reflex [27,28]. Bisacodyl has been widely prescribed for the management of neurogenic bowel [29]. The dosage is normally 5 or 10 mg, but up to

30 mg can be taken for complete cleansing of the bowel before a procedure. If it is taken at the maximum dosage, there will likely be a sudden, extremely powerful, uncontrollable bowel movement, and so precautions should be taken. When it is administered rectally in suppository form, it is usually effective in 15 to 60 minutes. Two suppositories can be inserted at once if a very strong, purgative, enema-like result is needed. A few hours after the initial evacuation, there can be a secondary action that will continue as long as there is unexpelled bisacodyl present in the rectum.

For design of the bowel program, a variety of factors need to be considered. Is this an upper motor neuron or lower motor neuron bowel dysfunction? Is it a complete or an incomplete lesion? Is this associated with anorectal dyssynergia? A detailed history is needed to find out any bowel problems antedating spinal cord injury, such as diabetes, irritable bowel syndrome, lactose intolerance, inflammatory bowel disease, or past rectal bleeding. These disorders may affect the management and choice of medications used in the bowel regimen. Other medications frequently used by patients with spinal cord injury for other problems, such as anticholinergics for treatment of neurogenic bladder, antidepressants, narcotics, and antispasmodic medications, also affect the bowel.

In addition, the person's dietary habits and the amount of fluid intake need to be documented as part of bowel management. It is helpful to evaluate psychosocial and family circumstances to provide guidelines to modify convenient timing for the bowel program and to develop rehabilitation strategies through diet, pelvic floor exercises, and biofeedback (in partial lesions).

Patient Education and Awareness of Risk Factors

It is critical to develop a comprehensive, individualized, and structured education program for prevention of incontinence, bowel accidents, and skin breakdown during sitting on a toilet seat. It is also important to identify other risk factors for negative outcomes: colonic overdistention, irritable bowel syndrome, bladder dysfunction, or autonomic dysreflexia in high spinal cord lesions. Equipment essential during bowel care also has been studied, although new technology in bowel chair design and manufacture has been slow to evolve [30,31]. There are flaws in commode-shower chair design, as reported by consumers, which increase the risk of falls during transfers and risk of pressure ulcers due to inadequate padding as well as the long duration of the bowel care process.

The current and most frequently used neurogenic bowel management strategies in some persons with only digital stimulation or a suppository insertion may be associated with incomplete evacuation, some incontinence, increased risk of pressure-induced tissue damage resulting from longer duration of commode sitting, and more damage to the mucosal tissue than with other methods available to persons with spinal cord injury. The use of the docusate mini enema may be an option in neurogenic bowel management because it has been shown to reduce the occurrence of bowel incontinence; it reduces the duration of commode sitting and thus reduces the risk of pressure ulcers, and it does not cause inflammation or seepage of the mucosal lining of the lower bowel [32]. All of these may improve quality of life and social and community integration of persons with spinal cord injury.

Use of Prokinetic Drugs

When conservative management is not effective, prokinetic agents, such as cisapride, prucalopride, metoclopramide, neostigmine, and fampridine, have been used and are supported by strong evidence for the treatment of chronic constipation in spinal cord-injured patients. They need to be used carefully for their side effects. Serious cardiac arrhythmias including ventricular tachycardia, fibrillation, and QT prolongation have been reported in patients taking cisapride. Cisapride has therefore been removed from the U.S. market [33–35]. The gastropromkinetic effects make metoclopramide useful in the treatment of gastric stasis and in gastroesophageal reflux disease. Because of the risk of tardive dyskinesia with chronic or high-dose use of the drug, the U.S. Food and Drug Administration recommends that metoclopramide be used for short-term treatment, preferably less than 12 weeks [35]; in 2009, it required all manufacturers of metoclopramide to issue a black box warning [35].

Procedures

Botulinum Toxin in Gastrointestinal Disorders

Botulinum neurotoxin inhibits contraction of gastrointestinal smooth muscles and sphincters; it has also been shown that the neurotoxin blocks cholinergic nerve endings in the autonomic nervous system, but it seems not to block noradrenergic responses mediated by nitric oxide. This has attracted use of botulinum neurotoxin for overactive smooth muscles, such as the anal sphincters for treatment of anal fissure and the lower esophageal sphincter for treatment of esophageal achalasia [36]. It is critical to appreciate the anatomic and functional organization of the denervation of the gastrointestinal tract for neuropathic bowel dysfunctions, particularly in patients with long-term constipation and incomplete bowel evacuation for whom a bowel rehabilitation program has failed. An early resolution of obstruction may be with botulinum neurotoxin to control the pelvic floor dyssynergic response. It might thus prevent back pressure effects on the rectosigmoid and colon in a neuropathic bowel.

Despite uncontrolled data, botulinum toxin is now being used for a variety of spastic disorders of gastrointestinal smooth muscle. Its usefulness has been exploited in anismus patients with pelvic floor dyssynergia. This is one of the common causes of constipation, in which the pelvic floor muscles contract too much or do not relax enough during a bowel movement. In one study [37], either 100 units of botulinum toxin (Botox; Allergan, Irvine, Calif) or 500 units (equivalent dose) of Dysport (Ipsen Ltd; Slough, United Kingdom) was diluted in 2 mL of normal saline, and a 21-gauge needle was passed cranially through the external sphincter to the level of the puborectalis muscle. The needle was then gradually withdrawn, injecting small amounts of mixture along the length of the puborectalis–external sphincter muscle; 1 mL was given bilaterally at the 3- and 9-o'clock positions. In these patients, initially 39% (21 patients) benefited, but after the second injection, 95% had resolution of symptoms. At a median follow-up of 19.2 (7.0–30.4) months, 20 (95%) of 21 patients had a sustained response and required no further treatment [37]. One unit of Botox is equivalent to about 3 units of Dysport. Most others have used only about 50 mg of Botox for anorectal injections.

So far, few placebo-controlled trials have been performed despite widespread use of the toxin for the past 10 years. Botulinum toxin appears to be safe, and side effects are uncommon. The short-term efficacy of intrasphincteric injection of botulinum neurotoxin in achalasia is now well established. The U.S. Food and Drug Administration has not approved Botox for any of these conditions.

Surgery

In patients with severe bowel dysfunction and markedly prolonged colon transit time [24], we evaluated indications for transverse colostomy [38]. In a follow-up study [39], the effect on quality of life of this procedure was evaluated with 100% satisfaction and reduction of bowel care from 117 minutes to 12.8 minutes per day ($P < .00001$). Indications for and usefulness of intestinal diversion have also been reported with positive results in patients with severe bowel dysfunctions after spinal cord injury [40]. In another study [41], the difference in the long-term outcome among left-sided colostomies, right-sided colostomies, and ileostomies was evaluated; The average daily time to bowel care was significantly shortened in all groups (right-sided colostomies, 102 to 11 minutes, $P < .05$; left-sided colostomies, 123 to 18 minutes, $P < .05$; and ileostomies, 73 to 13 minutes, $P < .05$). The successful outcome noted in all groups suggests that preoperative symptoms and colonic transit time studies may have been helpful in optimal choice of stoma site selection. However, the choice of colostomy in the descending colon was considered better because of the lesser fluid content in the fecal matter (more solid fecal matter) and the easy management of the collecting devices. In a systematic review of electronic databases (MEDLINE and CINAHL) from January 1960 to November 2007, colostomy in selected patients provided equivocal or superior quality of life outcomes compared with conservative bowel management strategies [11].

Surgical interventions, such as colostomy, Malone antegrade continence enema, and implanted stimulators [1,42], are not routinely used, although all are supported by lower levels of evidence (pre–post studies) in reducing bowel-related complications and improving quality of life. Overall, more intervention trials are needed to assess management programs for neurogenic bowel among individuals with spinal cord injury, especially trials involving multiple centers [1]. The use of common and validated scoring systems, such as the Neurogenic Bowel Dysfunction score and those found in the International Bowel Function data sets [43,44], will be helpful if they are implemented so that comparison of results and meta-analyses may be conducted to further our knowledge on the treatment and management of neurogenic bowel after spinal cord injury.

Potential Disease Complications

In spinal cord lesions above T6 level, one of the serious complications is autonomic dysreflexia. It usually accompanies poor bladder drainage and impacted fecal matter in the rectum. It needs immediate attention with gentle bowel evacuation after lidocaine jelly (4%) insertion in the rectum and use of alpha blockers to control blood pressure [11].

In a slow-transit bowel, marked abdominal distention with chronic constipation and dilated colon further aggravates bowel evacuation. A barium contrast enema will delineate an obstructing lesion, if it is present, or may reveal a huge colon with redundant bowel. Although this finding will not delineate the specific cause, it will indicate the magnitude of the anatomic abnormality. If the impaction is located more proximally in the bowel, oral stimulants, such as magnesium citrate solution or bisacodyl tablets, may be required. Caution in the use of oral medication is needed if a bowel obstruction is suspected. Intestinal perforation could result. In addition, oil retention enemas may be helpful in combination with oral agents to loosen the stool. The decision to proceed with colonoscopy depends on the individual's clinical history and findings as well as on whether the physician is satisfied with the results of the contrast enema. To clear the contrast material and to prevent constipation, oral laxatives and frequent bowel care should be used for a few days after studies that require barium [11].

Fecal incontinence can lead to overgrowth of microorganisms around the anus, which weakens the skin, and skin sores can develop. Also, sitting on an unpadded bowel care seat for a long time without frequent pressure relief could result in skin sores.

Hemorrhoids occur frequently [3] and may become more symptomatic as they increase in size; they may be exacerbated by physical interventions, such as suppositories, enemas, or digital stimulation, to regulate the bowels in individuals with spinal cord injury. When hemorrhoids become clinically significant, they may cause pain (if sensation is present), bleeding, mucus incontinence secondary to prolapsed mucosa, or symptoms of autonomic dysreflexia. Persistent bleeding and autonomic dysreflexia that are not responsive to changes in bowel care routine are indications for consideration of banding [45] or hemorrhoidectomy.

Potential Treatment Complications

In 27% of spinal cord-injured patients, chronic gastrointestinal problems appeared usually 5 to 10 years after the initial injury. This seems to be related mostly to anorectal dyssynergia with resultant obstructed constipation and incomplete evacuation with the back pressure effect on the colon [3], suggesting that these problems are acquired and may therefore be avoided by the adoption of certain chronic care routines to manage obstructed constipation with anal stretch, high-fiber diet, and adequate fluid intake. Chronic use of stimulant laxatives can lead to damage of the myenteric plexus with aggravated colonic dysmotility.

Definition

Osteoarthritis (OA) is generally considered a family of degenerative joint disorders characterized by specific clinical and radiographic findings. OA is the most prevalent chronic joint disease and has become the most common cause of walking disability in older adults in the United States [1–3]. It is estimated that 26.9 million adults have clinical OA, and the total cost for all arthritis, including OA, is more than 2% of the United States gross domestic product [4,5]. The

disease burden of OA is likely to continue to increase with the aging population and higher incidence of obesity [2,5].

OA has traditionally been thought of as just a condition of cartilage degeneration [6]. It is actually a complex combination of genetic, metabolic, biomechanical, and biochemical joint changes that lead to failure of the normal cartilage remodeling process (Fig. 139.1). The joint then accumulates increasing cartilage degeneration changes in response to stress or injury [2,6]. More recent evidence implicates bone changes and synovial inflammation also as integral to the pathologic process of OA [2]. As a whole, OA is characterized by degradation and loss of articular cartilage, hypertrophic bone changes with osteophyte formation, subchondral bone remodeling appearing as sclerosis or cysts, and chronic synovitis or inflammation of the synovial membrane [1,6].

Joint involvement in OA is usually asymmetric, with a predilection for weight-bearing joints. Common sites of involvement are the hips, knees, hands, feet, and spine. Less common sites of involvement are the ankles, wrists, shoulders, and sacroiliac joints. Secondary arthritis may be manifested with an atypical pattern of joint involvement.

OA is classified into two groups: primary and secondary. Primary or idiopathic OA can be localized or generalized. Localized OA usually refers to a single joint; generalized OA describes involvement of three or more joints. Secondary OA is due to a specific condition known to cause or to worsen development of OA (Table 139.1).

Multiple risk factors have been linked to the development of OA (Table 139.2). Systemic factors include age, gender, genetics, bone mineral density, and body weight. Age is consistently one of the strongest if not the strongest risk factor for OA [3,5]. Female gender is associated with higher prevalence of symptomatic knee, hip, and hand OA [3,5]. Heritable genetic traits may play a role in OA, but identification of such traits has been challenging. Some genetic markers strongly implicated in OA include *GDF5*, *MCF2L*, and the genomic region 7q22 [7,8]. There is an inverse relationship between bone mineral density and OA [3,9]. Both overweight and obese people are shown to be at a greater risk for OA, especially in weight-bearing joints like the knee [3,10,11]. Low levels of factors like vitamin C, vitamin D, vitamin E, and vitamin K may have an effect on OA, but there is no consensus recommendation currently [3].

Local biomechanical factors implicated in OA include previous joint injury, joint malalignment, bone anatomic

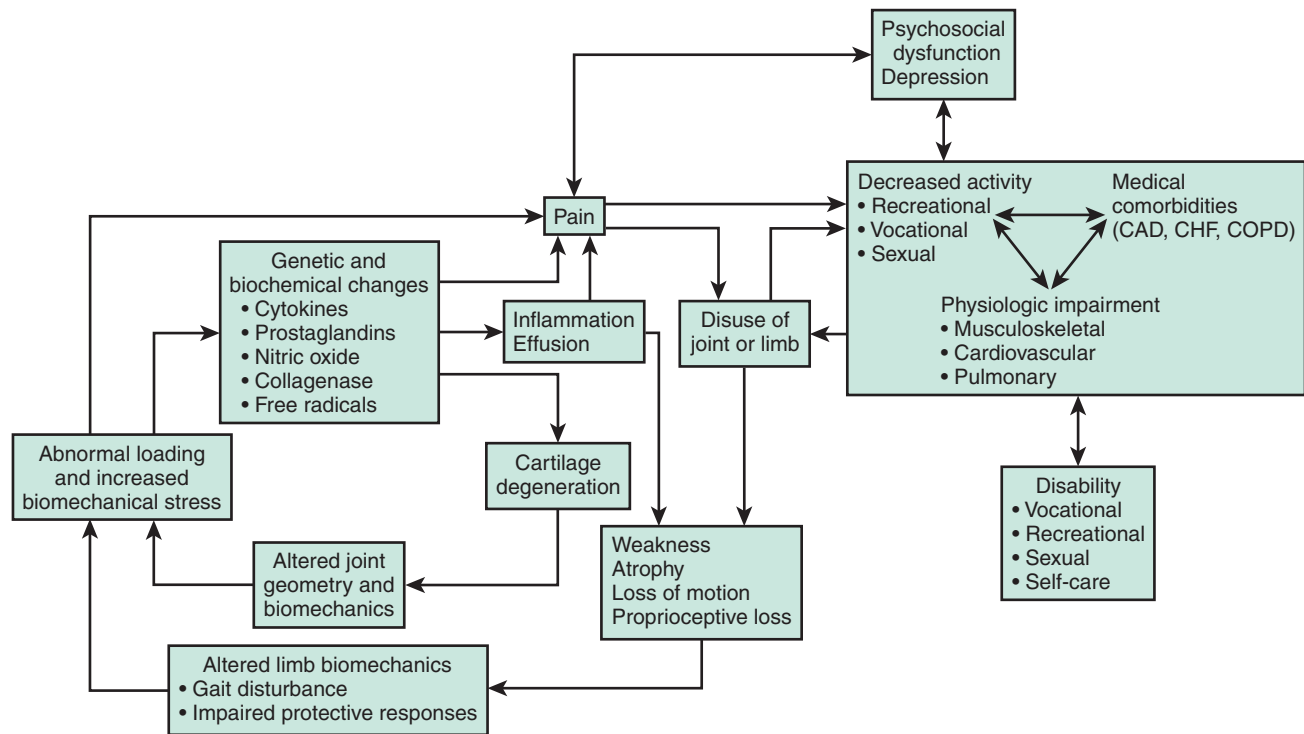

FIGURE 139.1 Model of multifactorial process of degeneration, pain, psychosocial and physiologic dysfunction, and disability that may occur in osteoarthritis. CAD, coronary artery disease; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease.

Table 139.1 Causes of Secondary Osteoarthritis

Bone and joint disorders, such as osteonecrosis and Paget disease

Biomechanical Factors

Joint injury
Joint malalignment
Bone variation or abnormality
Muscle weakness

variation or abnormality, and muscle weakness. Those with previous injury have a 15% greater lifetime risk of symptomatic knee OA [11]. Lower extremity malalignment may be associated with greater radiographic knee OA. Bone abnormality like acetabular dysplasia is associated with greater incidence of hip OA [12]. Muscle weakness, specifically of

the knee extensor muscles, predicts knee OA in most cohorts of women [3,13].

In terms of physical loading, some suggest that there is greater risk of knee OA with work activities such as squatting, lifting, prolonged standing, or climbing stairs, but this is not seen consistently [11]. Currently, there is no strong evidence to show that sports or physical activity itself leads to an increased risk of symptomatic OA [3]. Historical data have correlated certain sports with OA of specific joints, but there are many confounders in these studies that make interpretation inconclusive [3].

Symptoms

Patients usually complain of pain, stiffness, reduced movement, and swelling in the affected joints that is exacerbated with activity and relieved by rest. Pain at rest or at night suggests severe disease or another diagnosis. Early morning stiffness, if it is present, is typically less than 30 minutes. Joint tenderness and crepitus on movement may also be present. Swelling may be due to bone deformity, such as osteophyte formation, or an effusion caused by synovial fluid accumulation. Systemic symptoms are absent.

In early disease, pain is usually gradual in onset and mild in intensity. Pain is typically self-limited or intermittent. Patients with advanced disease may describe a sense of grinding or locking with joint motion and buckling or instability of joints during demanding tasks. Periarticular muscle pain may be prominent. Patients may complain of fatigue if biomechanical changes lead to increased energy requirements for activities of daily living. Overuse of alternative muscle groups can lead to development of pain syndromes in other parts of the musculoskeletal system.

Physical Examination

Joint Examination

Diagnosis of OA involves assessment of the affected joints for common clinical features (Table 139.3). These usually include tenderness, bone enlargement, and malalignment. Osteophytes, joint surface irregularity, or chronic disuse may also result in decreased range of motion, pain, effusion, and crepitus. Locking during range of motion may suggest loose bodies or floating cartilage fragments in the joint. Joint contracture can result from holding a joint in slight flexion, which is less painful for inflamed or swollen joints. There may be secondary abnormalities in joints above or below the primarily involved joint. Remember to assess joints bilaterally because asymptomatic joints may also have abnormal findings.

Neuromuscular and General Examination

A thorough musculoskeletal examination should include inspection, palpation of soft tissues surrounding the joint of interest, assessment of muscle strength and flexibility, and joint-specific provocative maneuvers. First, gait should be observed. There may be an antalgic gait or a slow gait pattern because of pain in a specific joint. If the patient uses a cane, appropriate use of the cane should be assessed during gait.

Both functional strength and manual muscle testing should be performed. Periarticular muscle atrophy and weakness may be present in chronic OA. However, manual muscle testing is typically unreliable in the lower extremities because of the high baseline strength of these muscle groups. Function tests like sit-to-stand testing may be more informative. Palpation and dynamic testing of soft tissues may differentiate pain from tendinopathy or bursitis from OA. Joint-specific provocative maneuvers may help isolate the source in symptomatic patients with poorly localized pain. A careful neurologic examination should be performed to ensure that pain is not the result of nerve impingement or a neuropathic process.

Clinicians may also consider performing a general examination. Evaluation of other systems may also help differentiate primary OA from secondary OA due to a systemic process. Because obesity has been identified as a risk factor for OA, assessment of the patient's body mass index may also be useful.

Functional Limitations

Functional limitations will depend on the joints affected by OA. Patients with disease in the hips and knees will have impairments in mobility, locomotion, and activities of daily living involving the lower body. Patients may complain

of increasing difficulty with climbing up and down stairs, walking, making chair or toileting transfers, and lower body dressing and grooming. Degeneration in the shoulders or hands limits vocational and recreational activities, self-care, and upper body activities of daily living. Patients may initially have trouble with using the computer or lifting boxes, which then progresses to difficulties with activities of daily living like feeding, grooming, bathing, and dressing. Spine OA can result in limitations with all mobility.

Diagnostic Studies

Although imaging studies are not needed to confirm the diagnosis, plain radiographs may help elucidate the severity of joint damage and progression of OA. The classic findings include asymmetric joint space narrowing, osteophytes at joint margins, subchondral sclerosis, and subchondral cyst formation. There is a well-demonstrated discordance between x-ray findings and symptoms in OA. Asymptomatic individuals may have significant radiographic disease, and severe pain and dysfunction can occur in the setting of limited radiologic changes. Computed tomography scans, ultrasonography, and magnetic resonance imaging are typically not needed for evaluation of OA but can be helpful in providing better visualization not only for OA severity evaluation but also for identification of other tissue pathologic processes and diagnosis [1].

Routine laboratory test results should be normal, and laboratory testing is usually not needed in uncomplicated cases of OA. If laboratory tests are available, clinicians should take care in interpreting the results. There is a high prevalence of laboratory abnormalities in elderly people, such as a raised erythrocyte sedimentation rate or anemia, because of comorbid conditions. Autoimmune markers may be useful to differentiate OA from other musculoskeletal disorders like inflammatory arthritides.

Joint aspiration should be pursued in patients with significant joint effusion or inflammation. Joint fluid analysis can be helpful in ruling out crystal deposition disease like gout or pseudogout, inflammatory arthritis, or infectious arthritis. In contrast to other arthritides, synovial fluid in OA is usually clear with normal viscosity and leukocyte counts typically less than 1500 to 2000 cells/mm³.

Neuropathy
Polymyalgia rheumatica
Inflammatory arthritis
Crystal deposit arthritis

Treatment

Initial

The major principles of OA management involve relieving pain and other symptoms as well as maximizing joint function and quality of life. Initial treatment should include both pharmacologic and nonpharmacologic rehabilitation modalities. Here we provide a broad overview of major concepts. Site-specific management of OA is discussed in more detail in other chapters.

No pharmacologic intervention has been shown conclusively to alter disease progression in OA. A number of topical and oral medications have been used to alleviate symptoms and to improve functional status. Topical treatment of OA includes nonsteroidal anti-inflammatory drugs (NSAIDs), capsaicin, rubefacients, and opioids. Many treatment guidelines from 2008 or later recommend topical NSAIDs as first-line OA treatment, especially in elderly patients, in whom drug safety and tolerability are significant concerns [1,14,15]. In a meta-analysis of 7688 participants in 34 studies, topical NSAIDs were significantly more effective than placebo in treating chronic musculoskeletal conditions such as OA [16]. Topical diclofenac is the only NSAID approved for use by the U.S. Food and Drug Administration. Studies of topical diclofenac in OA indicate a number needed to treat of 6.4 to 11 for at least 50% pain relief during 8 to 12 weeks compared with placebo [16]. Topical NSAIDs are recommended over oral NSAIDs by the American College of Rheumatology (ACR) for treatment of hand OA in patients older than 75 years [15].

Topical capsaicin cream has also been shown to reduce pain in joints affected by OA. This derivative of cayenne pepper causes exuberant release and depletion of substance P, which diminishes pain transmission from C fibers. Limited data from controlled trials have shown improvements in OA pain with capsaicin, and its use is recommended by the ACR and Osteoarthritis Research Society International as an adjunct or additional treatment [14,15].

Topical rubefacients containing salicylate or nicotinate esters are available for treatment of musculoskeletal pain without a prescription. They are thought to produce counterirritation and vasodilation of the skin for pain relief. Although they may be efficacious in the treatment of acute musculoskeletal pain in the short term (1 week), research on effectiveness is limited [17]. The ACR conditionally recommends trolamine salicylate as treatment of hand OA [15].

One randomized placebo-controlled trial looked at the use of transdermal fentanyl in moderate to severe OA [18]. Although there may be some pain relief, use of transdermal opioids is not routinely recommended because of the potential negative effects of opioid use [18–20].

Oral agents often discussed in the treatment of OA include acetaminophen, NSAIDs, opioids and opioid-like medications, serotonin-norepinephrine reuptake inhibitors, and glucosamine and chondroitin. Acetaminophen and NSAIDs are typically considered first-line oral agents [1,14,15]. A meta-analysis of acetaminophen demonstrated a statistically significant reduction in pain compared with placebo in seven randomized controlled trials with a number needed to treat of 4 to 16 [21]. Although NSAIDs are more efficacious than acetaminophen, effects were modest

and associated with greater rates of adverse gastrointestinal effects [21].

Tramadol acts not only as a weak opioid but through modulation of serotonin and norepinephrine levels. A meta-analysis of 11 randomized controlled trials with a total of 1019 patients showed less pain intensity, greater symptom relief, and improved function for those receiving some form of tramadol compared with placebo or control. However, adverse effects were often noted to cause patients to stop taking the medication [22]. Tramadol alone or in combination with acetaminophen is conditionally recommended by the ACR as initial treatment of OA in several joints [15].

The use of opioid medications in OA has risen. Although opioids can improve pain and function in patients with OA, there is a high rate of adverse events and withdrawal of patient treatment [1,20]. Opioids should be considered second-line treatment at best, even when OA pain is severe [20]. The ACR strongly recommends use of opioids only for patients who are either not willing to undergo or have contraindications to total knee arthroplasty after medical therapy has failed [15].

Duloxetine is a serotonin-norepinephrine reuptake inhibitor that is conditionally recommended by the ACR for treatment of knee OA [15]. In pooled data from two randomized controlled trials, patients with knee OA treated with duloxetine were more likely to experience an improvement in outcomes, pain, and function with a number needed to treat of 5 to 9 [23].

Significant attention has focused on the use of supplements such as chondroitin and glucosamine in OA. The Glucosamine/chondroitin Arthritis Intervention Trial (GAIT), a randomized controlled trial of 1583 patients with painful knee OA, demonstrated no clinically significant effective pain reduction [24]. Multiple other randomized controlled trials and meta-analyses of both chondroitin and glucosamine have had conflicting conclusions, and the topic is still hotly debated [1,25–27]. The ACR conditionally recommends against the use of chondroitin and glucosamine in knee OA and hip OA [15]. Patients considering the use of glucosamine or chondroitin should be cautioned that these products are not subject to regulation of purity or accuracy of labeling.

Other treatments of OA include avocado soybean unsaponifiables and diacerein, but these are not widely used [1].

Rehabilitation

A comprehensive rehabilitative approach is important and effective in promoting wellness and reducing disability in patients with OA.

Self-management interventions and programs foster active participation of patients and are thought to be a key element of chronic disease management [1]. These programs provide education and experiential skills in not only disease management but mental and social well-being. Studies have demonstrated that these interventions reduce pain, improve health behaviors, and reduce use of health care resources in patients with chronic pain and arthritis [28]. Group-based self-management programs are often available through a local chapter of the Arthritis Foundation and are conditionally recommended by the ACR for patients with hip and knee OA [15].

Lifestyle changes like exercise and weight loss are an integral part of rehabilitation of OA. There is significant evidence that physical activity is important in patients with OA. Both aerobic and muscle strengthening exercises seem to be beneficial in terms of improving pain, function, and quality of life [29–32]. A meta-analysis of 32 studies indicates platinum level [33] of evidence that land-based therapeutic exercises have at least short-term benefit for reduction of pain and improved physical function for knee OA [34]. There is silver level [33] of evidence for land-based therapeutic exercises for reduction of pain and improvement of physical function in symptomatic hip OA [35]. Therapeutic exercises should include joint protection techniques, stretching and range of motion exercises, muscle strengthening, and aerobic exercises.

Weight loss is important in overweight patients with OA. A meta-analysis of weight reduction in patients with knee OA showed diminished physical disability with a weight loss of more than 5% within a 20-week period [36].

The ACR strongly recommends land-based cardiovascular (aerobic) and resistance exercises, aquatic exercises, Tai Chi, and weight loss (in persons overweight) for patients with OA of hip and knee [15]. Physiatrists, occupational therapists, physical therapists, and other health care professionals can help make recommendations on appropriate exercise, weight loss techniques, and therapeutic modalities for individualized patient care.

Clinical experience suggests that cold, heat, and manual therapy can be helpful in decreasing pain and increasing mobility. Thermal agents and manual therapy in combination with supervised exercise are also recommended by the ACR [15].

Braces and splints may be helpful for symptomatic relief of certain joints. Knee bracing had additional benefit compared with medical treatment alone on the basis of limited evidence [37]. Splints may be useful for OA of the thumb [38]. The ACR recommends splinting for patients with hand OA, specifically of the trapeziometacarpal joint, but offers no recommendations on knee bracing [15].

Orthotic wedged insoles and medially directed patellar taping may be helpful for knee OA to off-load the joint or to improve biomechanics.

Adaptive equipment, such as a cane or walker, can be used if necessary for patients with impaired balance to prevent falls or for pain reduction by decreasing joint loading. In the setting of significant functional impairments, therapists can provide assistive devices that help with feeding, grooming, dressing, and other activities of daily living.

The use of transcutaneous electrical nerve stimulation is supported by a few small, short-term trials. Systematic review of the data has been inconclusive [39]. For most patients in these studies, pain relief was experienced only during active use of the device. Regardless, transcutaneous electrical nerve stimulation is conditionally recommended by the ACR in knee OA [15]. Ultrasound appears to have no proven benefit in the treatment of OA.

Acupuncture is also recommended for the treatment of chronic moderate to severe painful knee OA. A multicenter, 26-week National Institutes of Health–funded randomized controlled trial found acupuncture to be effective as adjunctive therapy for reducing pain and improving function in patients with knee OA [40]. A meta-analysis of acupuncture

in the treatment of OA showed statistically significant benefits compared with sham or waiting list controls [41].

Procedures

Intra-articular corticosteroid injection is conditionally recommended by the ACR for patients with painful knee or hip OA who do not have a satisfactory clinical response to full-dose acetaminophen [15]. The short-term effect of intra-articular corticosteroid injection has been well demonstrated in meta-analysis, and it is routinely used in treatment of OA [42,43]. There is clinically significant improved pain relief and patient global assessment compared with placebo injections, although the effects typically last only 1 to 3 weeks [42,43].

Intra-articular hyaluronic acid injections (viscosupplementation) are conditionally recommended by the ACR for people 75 years of age or older with knee OA but are not routinely recommended for OA of other joints [15]. Although conflicting evidence exists, multiple meta-analyses of randomized controlled trials suggest that there may be a small benefit in comparison with intra-articular placebo injection or noninterventional control [43,44]. The clinical significance is difficult to determine and may be irrelevant. In comparison with glucocorticoid injections, hyaluronic acid injections had greater benefit between 5 and 13 weeks after injection, but this was not sustained [43].

Procedures such as botulinum toxin type A injection, intra-articular injection of platelet-rich plasma, and adipose stem cell injections are under investigation [42,45–48]. A few studies showed positive effect of platelet-rich plasma in patients with knee OA, but no standardized protocol has been established [47,48].

Surgery

In patients for whom pain and loss of mobility are disabling despite conservative management, orthopedic consultation should be obtained to assess risks and benefits of surgery.

Surgical interventions performed for OA include arthroscopic lavage and débridement, osteotomy, joint fusion, joint distraction, and arthroplasty. Joint replacement surgery or total joint arthroplasty is a mainstay of surgical OA treatment. Protocols for total joint arthroplasty include different approaches and minimally invasive techniques. A systematic review of hip replacement surgery trials concluded that in 70% of subjects, pain and function scores were rated good or excellent 10 years postoperatively [49]. Observational studies have suggested that better outcomes are associated with patients between the ages of 45 and 75 years; with weight less than 70 kg; and with a good social support, higher educational level, and lower preoperative morbidity [50]. Similar favorable results have been achieved in total knee replacement for OA. In both hip and knee joint replacements, early inpatient rehabilitation after arthroplasty has been shown to reduce hospital stays and cost of care in older patients with medical comorbidities [51].

Systematic review of arthroscopic lavage and débridement in OA showed no short- or long-term benefit compared with placebo, and it is not advised [52]. Osteotomy has been used to correct biomechanics and to unload areas of high stress with some success. Fusion may be helpful in

situations in which joint replacement is not appropriate. Joint distraction or distraction arthroplasty is increasingly performed for ankle OA to avoid fusion and to maintain range of motion. Hip joint resurfacing is an effective alternative to total arthroplasty in severe hip OA [53], but patellar resurfacing is not recommended in knee pain, for which no benefit has been shown [54].

Potential Disease Complications

Potential complications of OA include chronic pain, muscle weakness, decreased range of motion, limited physical function, inability to participate in work or the community, and loss of self-care skills.

Potential Treatment Complications

The safety profile of topical OA medications is generally good. Topical NSAIDs may cause increased local adverse events (mostly mild skin reactions) compared with placebo or oral NSAIDs [16]. However, topical NSAIDs have decreased incidence of gastrointestinal, cardiovascular, and renal adverse events compared with traditional oral NSAIDs [15,16]. Topical capsaicin and rubefacients are known for local skin reactions like redness, burning pain, and itching. It is worthwhile to caution patients that they may experience increased pain when beginning therapy.

Oral analgesics including acetaminophen and NSAIDs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Although use of acetaminophen is associated with only mild side effects for the most part, it does carry a significant risk of hepatic toxicity. NSAIDs are known to have both gastrointestinal toxicity and nephrotoxicity and are associated with increased risk of myocardial infarction, stroke, and erectile dysfunction. In patients with high gastrointestinal risk for ulceration and bleeding, a cyclooxygenase-2 inhibitor or NSAID with concurrent use of a proton pump inhibitor may be considered [1]. Selective cyclooxygenase-2 inhibitors carry greater cardiovascular risk and should be used only in patients with minimal cardiovascular risk factors and no history of cardiovascular disease. The most common adverse drug reactions of tramadol and opioids are nausea, vomiting, itching, sweating, constipation, and drowsiness. Drug addiction and dependence with both are widely reported.

All intra-articular injections usually have mild side effects but, like any procedure, may result in bleeding, infection, and local irritation and pain. Complications common to all surgical techniques include pain, bleeding, infection, and effects of anesthesia. Studies have well documented the adverse effects or events associated with total arthroplasty. Intraoperative complications include fracture, nerve injury, vascular injury, and cement-related hypotension. Postoperative complications of total joint arthroplasty include thromboembolism, dislocation, osteolysis, aseptic loosening, implant failure or fracture, and heterotopic ossification. Aseptic loosening, implant failure, and fractures are often painful and require surgical revision.

ICD-9 Code

733.00 Osteoporosis, unspecified

ICD-10 Code

M81.0 Age-related osteoporosis without current pathological fracture, osteoporosis NOS

Definition

Osteoporosis is a skeletal disorder characterized by compromised bone strength predisposing a person to an increased risk for fracture. Bone strength primarily reflects the integration of bone density and bone quality. Bone quality refers to factors such as microarchitectural changes, bone turnover, collagen structure, damage accumulation (e.g., microfractures), and degree of mineralization [1].

Osteoporosis can also be defined according to the World Health Organization criteria on the basis of bone mineral density and bone mineral content measurements (see section on diagnostic studies).

Osteoporosis is the most common metabolic bone disease. The National Osteoporosis Foundation estimates that at least 10 million Americans have osteoporosis and another 34 million have decreased bone mass, putting them at increased risk for osteoporosis and fractures. Of the 10 million, 8 million are women and 2 million are men. Annually in the United States, more than 1.5 million fractures attributable to osteoporosis occur, including approximately 750,000 vertebral, 300,000 hip, and 250,000 wrist fractures. The annual cost of caring for osteoporosis-related fractures in the United States is in excess of \$16 billion. In addition, there is a 15% to 25% excess mortality within the first year after a hip fracture. In recent years, the hip fracture rate has been reported to be declining [2].

Symptoms

Osteoporosis is a silent disease until a fracture occurs. Pain and deformity are usually present at the site of fracture. Vertebral fractures often occur with little trauma, such as coughing, lifting, or bending over. Acute back pain may be related to a vertebral compression fracture, with pain localized to the fracture site or in a radicular distribution. New back pain or chronic back pain in a patient with osteoporosis and prior vertebral fractures may be related to new fractures, muscle spasm, or other causes.

With vertebral fractures, even if they are asymptomatic, there may be a gradual loss of height and the development of a kyphosis. Breathing may be difficult, and early satiety and bloating—a sensation of fullness and dyspepsia—may develop because of less room in the abdominal cavity.

Physical Examination

In evaluating patients with osteoporosis, it is important to diagnose treatable and reversible causes and to assess the risk factors for development of osteoporosis and osteoporotic fractures. Table 140.1 lists common causes of osteoporosis. Table 140.2 lists risk factors for osteoporosis.

The physical examination focuses on findings suggestive of secondary causes of osteoporosis (e.g., hyperthyroidism and Cushing syndrome). One should also examine areas previously involved with fractures (e.g., back, hip, and wrist) to assess for deformity and limitation of function. A baseline measurement of height should be obtained and reevaluated at subsequent visits. Localized vertebral tenderness may be present from fracture, paravertebral muscle spasm, or exaggerated thoracic kyphosis. The findings of the neurologic examination looking for any deficits due to vertebral fracture are usually normal.

Functional Limitations

Functional limitations are related to the type of fracture and its long-term consequences. With vertebral fractures, the functional limitation may initially be related to the acute pain and inability to move. The chronic limitations may be related to loss of height, chronic back pain, difficulty in moving, abdominal distention, and difficulty in breathing.

The functional limitations after a hip fracture are related to the decreased functional mobility, often the need for long-term use of assistive devices, the lack of independence, and the long-term need for assistive care. An assistive device will be needed permanently for ambulation by

50% of people with a hip fracture, and two thirds will lose some of their ability to perform ordinary daily activities.

Wrist fractures usually heal completely, but some people have chronic pain, deformity, and functional limitations.

Diagnostic Studies

Bone density measurements are the standard for assessment of risk, diagnosis, and long-term management of patients with osteoporosis. Bone density measurement is often essential to

make management decisions. Available techniques include single-photon absorptiometry, dual-energy x-ray absorptiometry, quantitative computed tomography, and quantitative ultrasonography. Dual-energy x-ray absorptiometry, although it is not as sensitive as quantitative computed tomography for detection of early trabecular bone loss, is the method of choice for measurement of bone mineral density because of its good precision, low radiation dose, and fast examination time.

Bone mineral density testing should be based on an individual's fracture risk profile and skeletal health assessment. It should be performed only if the results will influence a treatment decision.

Bone mineral density testing should be considered on the basis of the National Osteoporosis Foundation guidelines, as follows [3]:

- Women age 65 and older and men age 70 and older, regardless of clinical risk factors
- Younger postmenopausal women and men age 50-69 about whom you have concern based on their clinical risk factor profile
- Adults who have a fracture after age 50
- Adults with a condition (e.g., rheumatoid arthritis) or taking a medication (e.g., glucocorticoids in a daily dose of 5 mg or more for >3 months) associated with low bone mass or bone loss
- Anyone being considered for pharmacologic therapy for osteoporosis
- Anyone being treated for osteoporosis, to monitor treatment effect
- Anyone not receiving therapy in whom evidence of bone loss would lead to treatment
- Postmenopausal women discontinuing estrogen

Bone mineral density is reported by T and Z scores (Table 140.3). The T score compares an individual's bone mineral density with the mean value for young normal individuals expressed as a standard deviation (SD); the Z score compares the values to age- and sex-matched adults.

- Normal: a T score value for bone mineral density or bone mineral content that is not more than 1 SD below the young adult mean value.
- Low bone mass (osteopenia): a T score value for bone mineral density or bone mineral content that lies between 1.0 and 2.5 SDs below the young adult mean value.
- Osteoporosis: a T score value for bone mineral density or bone mineral content that is 2.5 SDs or more below the young adult mean value.

The lower the T score, the higher the risk for subsequent fractures. However, the score will not predict who will fracture because other factors come into play (e.g., fall velocity, type of fall, direction of fall, and protective padding). A low Z score may suggest excessive bone loss due to secondary causes of osteoporosis.

Specific laboratory tests are obtained to help in the differential diagnosis of osteoporosis and to rule out osteomalacia. The general laboratory tests include a complete blood count,

Table 140.3 Bone Mineral Density Reporting

T score	Standard deviations (SDs) above or below peak bone mass in young, normal, sex-matched adults
Z score	Standard deviations (SDs) above or below age- and sex-matched adults

chemistry profile including calcium and phosphorus, liver and kidney tests, serum and urine protein electrophoresis, and thyroid-stimulating hormone concentration. A 24-hour collection of urine for calcium and creatinine measurement is also helpful. Because of the high prevalence of vitamin D deficiency in the adult population, especially elderly individuals, a serum 25-hydroxyvitamin D level should be obtained. A parathyroid hormone level should be determined in suspected cases of primary or secondary hyperparathyroidism. Blood and urine test results are usually normal in uncomplicated cases of osteoporosis. After a fracture, the alkaline phosphatase activity may be elevated. Biochemical markers of bone turnover, including urine N-telopeptide and serum C-telopeptide, may be helpful in selective patients to assess for bone turnover and whether someone is responding to treatment.

Differential Diagnosis

Common causes of osteoporosis are listed in [Table 140.1](#).

Treatment [4]

Initial

The initial approach to the prevention and treatment of osteoporosis involves nonpharmacologic interventions and, in appropriate patients, the use of various pharmacologic agents ([Table 140.4](#)). Prevention and treatment guidelines are presented in [Tables 140.5](#) and [140.6](#).

Calcium

Adequate calcium is important for all age groups. Epidemiologic studies suggest that long-standing dietary calcium deficiency can result in lower bone mass. The average dietary calcium intake in postmenopausal women is less than 600mg/day. Several studies have shown that calcium supplementation along with vitamin D, especially in the elderly, may slow bone loss and reduce vertebral and nonvertebral fracture rates [5]. A total calcium intake of

Pharmacologic Agents

Hormone replacement therapy
Selective estrogen receptor modulators
Raloxifene (Evista)
Bisphosphonates
Alendronate (Fosamax)
Risedronate (Actonel)
Ibandronate (Boniva)
Zoledronic acid (Reclast)
Calcitonin (Miacalcin and Fortical nasal sprays)
Teriparatide (Forteo)
Denosumab (Prolia)

Table 140.5 Osteoporosis Prevention Guidelines

Hormone replacement therapy for menopausal symptoms
Raloxifene, 60 mg/day
Alendronate, 5 mg/day or 35 mg once weekly by mouth (prevention dose)
Risedronate, 5 mg/day or 35 mg weekly or 150 mg monthly by mouth
Ibandronate, 2.5 mg daily or 150 mg monthly by mouth
Zoledronic acid, 5 mg intravenously every other year

Table 140.6 Osteoporosis Treatment Guidelines

Alendronate, 10 mg/day or 70 mg once weekly (treatment dose)
Risedronate, 5 mg/day or 35 mg weekly or 150 mg monthly by mouth
Ibandronate, 2.5 mg/day or 150 mg monthly orally; 3 mg intravenously every 3 months
Zoledronic acid, 5 mg intravenously yearly
Raloxifene, 60 mg/day
Calcitonin (nasal spray), 200 units once daily
Teriparatide, 20 µg subcutaneously daily for 2 years
Denosumab, 60 mg subcutaneously every 6 months

1200 to 1300mg/day is recommended for postmenopausal women [6]. This can be achieved primarily by consumption of foods that have a high calcium content, such as milk and dairy products and calcium-fortified foods, especially yogurt. Calcium supplementation is often required, especially in elderly individuals. Calcium carbonate supplements have the highest calcium content but may cause abdominal discomfort with bloating and constipation and are better absorbed when they are taken with foods. Calcium citrate preparations are generally better absorbed and are not dependent on gastric acid.

Vitamin D

Vitamin D insufficiency and deficiency are common in postmenopausal women, especially in those who have sustained a hip fracture and those who are chronically ill, housebound, institutionalized, and poorly nourished [6,7]. Vitamin D improves muscle strength and balance and reduces the risk of falling. There may also be other unproven nonskeletal beneficial effects. A dose of 800 to 1000IU/day (from supplements, multivitamins, and other sources) should be administered to prevent vitamin D deficiency. Some need higher amounts. Many calcium supplements now contain vitamin D. Maintaining a serum 25-hydroxyvitamin D level of more than 30ng/mL (70nmol/L) is suggested by many experts, although the Institute of Medicine suggests levels above 20ng/mL.

Exercise

There is increasing evidence that weight-bearing and strength training exercises are beneficial to bone in helping achieve peak bone mass and preserving bone later in life [8]. Bone adapts to physical and mechanical loads placed on it by altering its mass and strength. This occurs either by the direct impact from the weight-bearing activity or by the action of muscle attached to bone. Exercising can also help strengthen back muscles, improve balance, lessen the likelihood of falling, and give one a sense of well-being [9]. Back

extension exercises and abdominal strengthening exercises are helpful. However, acute stresses to the back, such as trunk flexion, side-bending, high impact, and heavy weights, should be avoided to lessen the likelihood of injury and fracture. A proper exercise program should be established. Older postmenopausal women and even the frail elderly can tolerate and potentially show improvements in muscle strength and bone mineral density in response to strength training and resistive exercise programs.

Smoking Cessation

A 5% to 10% reduction in bone density has been seen in women who smoked one pack per day in adulthood. Therefore, it is recommended that physicians aggressively pursue smoking cessation in their treatment plans.

Fall Prevention

Many factors can lead to falls, including poor vision, frailty, medication (especially narcotic pain medications, hypotensive agents, and psychotropic drugs), and balance disturbances [10]. Each area needs to be assessed appropriately. Prevention measures include keeping rooms free from clutter and having good lighting. Advise patients to wear supportive shoes, to be aware of thresholds, and to avoid slippery floors; rugs should be tacked down. Grab bars are useful in the bathroom. A portable telephone and a personal alarm activator are helpful, and someone should check on the individual regularly.

Guidelines for Treatment

The guidelines for treatment of postmenopausal women based on National Osteoporosis Foundation recommendations are as follows:

- Hip or spine fracture
- T score -2.5 or below at the spine, femoral neck, or total hip
- T score between -1.0 and -2.5 and high 10-year fracture risk by the U.S.-adapted World Health Organization Fracture Risk Assessment Calculator (FRAX). Treat if 10-year risk is 3% or more for hip fractures or 20% or more for major osteoporosis-related fractures [11].

Hormone Replacement Therapy

Hormone replacement therapy can be used in the short-term management of postmenopausal women with symptoms of estrogen deficiency, including hot flashes, memory deficits, urinary frequency, and vaginal dryness. Long-term hormone replacement therapy can slow bone loss and lower the incidence of fractures [12]. In the Women's Health Initiative (WHI) study with estrogen and progestin, there was a 34% reduction in vertebral and hip fractures. However, there was an increase in breast cancer, coronary heart disease, stroke, and thromboembolic disease [13]. The mean age of patients in the WHI was 63 years. A recent reanalysis from the WHI showed no increase in coronary heart disease risk in women when hormone replacement therapy was started within 10 years of the onset of menopause [14]. Significant controversy still exists about the results of the WHI. Estrogen is approved for the prevention of osteoporosis but not for treatment. The major reason to use hormone replacement therapy is to treat menopausal symptoms. The lowest dose

of estrogen and progesterone should be used to effectively relieve these symptoms. Women who have had a hysterectomy should be given estrogen alone. A progestin should be added to the estrogen regimen if the uterus is still present.

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators are synthetic compounds that have both estrogen-antagonistic and estrogen-agonistic properties. Raloxifene (Evista) is approved by the Food and Drug Administration (FDA) for the prevention and treatment of osteoporosis at an oral dose of 60 mg daily. Raloxifene is also approved for the reduction in risk of invasive breast cancer in postmenopausal women with osteoporosis and in postmenopausal women at high risk of invasive breast cancer. Raloxifene reduces new vertebral fractures by 40% to 50% but not the risk of nonspine fractures [15]. Raloxifene acts as an antiestrogen on breast tissue and reduces the risk of invasive breast cancer similar to the reduction by tamoxifen. It does not produce uterine hypertrophy and does not significantly affect the risk of coronary heart disease. Raloxifene has no beneficial effects on menopausal symptoms and may increase hot flashes and the risk of deep venous thrombosis.

Bisphosphonates

The bisphosphonates are a group of compounds related chemically to pyrophosphate. They are characterized by a P-C-P structure. Changes in the side chains affect the binding and potency of the bisphosphonates. They are potent inhibitors of osteoclastic bone resorption.

Alendronate (Fosamax) was the first approved by the FDA in 1995 for the prevention and treatment of postmenopausal osteoporosis. Alendronate is also approved for the treatment of glucocorticoid-induced osteoporosis [15] and osteoporosis in men. In postmenopausal women, the dose for prevention is 5 mg/day or 35 mg once weekly; the dose for treatment is 10 mg/day or 70 mg once weekly. Alendronate significantly increases bone mineral density at various sites. In addition, there is a significant decrease in the incidence of vertebral, hip, and wrist fractures as well as painful vertebral fractures, hospitalization days, and other measurements of functional impairment [16].

Risedronate (Actonel) is approved by the FDA for the prevention and treatment of postmenopausal osteoporosis with an oral dose of 5 mg daily, 35 mg weekly, or 150 mg monthly. Studies have shown an increase in bone mineral density at various sites along with a decrease in vertebral and nonvertebral fractures [17]. Risedronate is also approved for the prevention and treatment of glucocorticoid-induced osteoporosis and osteoporosis in men.

Ibandronate (Boniva) is approved by the FDA for the prevention and treatment of postmenopausal osteoporosis. The oral dose is either 2.5 mg daily or 150 mg monthly. An intravenous preparation is also available for the treatment of postmenopausal osteoporosis in a dose of 3 mg intravenously every 3 months. Studies have shown an increase in bone density and a reduction in vertebral fractures [18].

The bisphosphonates are poorly absorbed and must be given on an empty stomach to maximize their absorption. Alendronate and risedronate must be taken at least 30 minutes (ibandronate, 60 minutes) before the first food, beverage, or medication with a full glass of plain water, and

patients should not lie down for at least 30 minutes (ibandronate, 60 minutes) to avoid the potential upper gastrointestinal side effects, especially of esophagitis. Patients with a history of reflux should not be given these medications.

Zoledronic acid (Reclast) is approved by the FDA for the treatment of postmenopausal osteoporosis, osteoporosis in men, and glucocorticoid-induced osteoporosis and after surgical repair of hip fracture. It is administered as a once-yearly infusion of 5 mg, administered usually during 15 to 20 minutes. It significantly reduces spine, hip, and nonhip fractures and increases bone density [19].

The major side effects with the intravenous bisphosphonates are the acute phase symptoms, including fever, muscle and joint pains, influenza-like symptoms, and headache. These usually last for no more than 24 to 72 hours. These symptoms have been reported in 32% of patients with the first infusion, in 7% after the second yearly infusion, and in 3% after the third infusion of zoledronic acid. Very uncommon but serious adverse complications from long-term use of the bisphosphonates include osteonecrosis of the jaw [20] and atypical femur fractures [21]. Osteonecrosis of the jaw has been reported primarily in cancer patients who receive bisphosphonates for skeletal metastases at a dose much higher than the dose given for osteoporosis.

Calcitonin

Synthetic salmon calcitonin given parenterally by injection and nasal spray (Miacalcin, Fortical) is approved for the treatment of postmenopausal osteoporosis. The injectable calcitonin is given as 100 units daily subcutaneously or intramuscularly. The nasal spray of calcitonin is approved in a dose of 200 units (one spray) daily. A reduction in new vertebral fractures but not in hip or nonvertebral fractures has been reported [22]. Occasional nasal irritation or headache may be seen with the nasal spray.

Parathyroid Hormone

As long ago as the late 1920s, there was evidence that parathyroid extract, administered in an intermittent once-a-day injection, stimulated osteoblast activity in animal models. This is in contrast to bone loss seen with chronic elevations in parathyroid hormone in primary hyperparathyroidism. After human parathyroid hormone was sequenced in the early 1970s, clinical studies with use of the 1-34 amino-terminal fragment started. Early results in osteoporosis trials showed increases in bone accretion, calcium balance, and trabecular bone volume with normal skeletal architecture. In the multicenter trial of recombinant human parathyroid hormone 1-34 fragment (teriparatide), 20 µg administered subcutaneously daily produced an increase in vertebral and hip bone density and a 55% reduction in vertebral fracture risk [23]. Teriparatide (Forteo) is generally well tolerated and is self-administered for up to 2 years by use of a 31-gauge needle and a prefilled syringe with a 28-day supply of medication. It is currently the only anabolic agent available (in contrast to the antiresorptive agents) and is approved for the treatment of postmenopausal women with osteoporosis who are at high risk for fracture. It is also approved for treatment of osteoporosis in men and glucocorticoid-induced osteoporosis. In rats given teriparatide in doses up to 60 times the exposure in humans, there was an increase in osteosarcoma, which was dose and duration

dependent. Thus, teriparatide should not be administered to patients who have an increased baseline risk for osteosarcoma, including patients with Paget disease of bone, those with unexplained elevated alkaline phosphatase, and those who have received prior external beam or implant radiation therapy involving the skeleton.

Denosumab

Denosumab (Prolia) is a human monoclonal antibody directed against RANKL, a cytokine mediator responsible for accelerating osteoclast formation. It is approved for the treatment of postmenopausal osteoporosis at high risk for fractures and osteoporosis in men. The dose is 60 mg subcutaneously every 6 months. Reductions in spine, hip, and nonspine fractures are seen, and there is an increase in bone density. Side effects include a small increase in serious infection, such as skin infections. It is not affected by renal function and can be given to patients with reduced renal function [24].

Rehabilitation

Rehabilitation efforts in osteoporosis should commence long before a fracture. Either a physical or occupational therapist can be involved in assessing the patient's home to make sure it is safe and to decrease the risk of falls. Specialized equipment, such as grab bars for the bathroom and hand-held reachers for high cupboards, can be very helpful. It is important to educate patients about keeping the floors clear of clutter and throw rugs. Small pets also can be a hazard underfoot.

Therapists can assess whether the patient would be safer ambulating with an assistive device (e.g., cane or walker) in the home and community. It is important for all assistive devices to be appropriately prescribed and fitted for the patient.

Finally, therapists can instruct patients about how to exercise to improve strength, flexibility, and balance. All of these activities can help prevent falls, and weight-bearing strengthening exercises may also improve bone density.

In patients with a hip fracture or other disabling fracture, a multidisciplinary coordinated team approach involving the physician, therapists, and other rehabilitation specialists (e.g., nurse, social worker) is necessary for the patient to regain maximal function and to lead a productive life. The initial rehabilitation program also involves pain control, bowel and bladder care, and maintenance of skin integrity. The therapists, in addition to working on a program involving bed mobility, transfers, gait activities, safety precautions, and activities of daily living, must be cognizant of the medical problems in each patient. After an acute rehabilitation stay, some patients may need an additional stay in a transitional setting on their way to eventually going home or else require long-term placement. For those able to go home, the team needs to teach the patient a home exercise program, to order appropriate equipment, and to arrange for continued therapy, either at home or in an outpatient setting.

Back Braces

Back braces may be helpful, especially in the short term, to get patients out of bed and ambulatory so they can participate in activities. Back braces, however, can be very uncomfortable and often are not tolerated. Long-term use

should be discouraged unless it helps the patient in functional activities and with control of pain.

Procedures

Other than surgery for fracture repair, procedures are generally not needed in the management of osteoporosis. Two procedures—vertebroplasty and kyphoplasty—are available to stabilize vertebral fractures and to alleviate pain.

Surgery

The preferred treatment of hip fracture and some other fractures is surgical repair and stabilization.

Potential Disease Complications

As bone density decreases, the risk for sustaining a fracture increases. Osteoporosis is asymptomatic until a fracture occurs. Thereafter, all complications are related to the problems from these fractures, to the surgery (if it is required), and to the recuperative period and eventually to the loss of function and independence.

After vertebral fractures, acute pain may limit mobility. Bed rest and narcotic analgesics may be necessary. Severe constipation and urinary retention may ensue. Chronically, patients may suffer from severe back pain and have respiratory problems, abdominal distention, bloating, and constipation. Many patients who wear a back brace complain about the discomfort and difficulty in using it.

Potential Treatment Complications

The complications of treatment can be related either to the surgical repair of the fracture and the recuperative phase or to medications used to prevent or to treat osteoporosis.

Most osteoporotic fractures occur in older patients and result in loss of function and loss of independence and the need for long-term care. Because surgery is required to repair a hip fracture, complications from surgery, anesthesia, bed rest, and pain medications (often narcotics) are common. Pneumonia, phlebitis, urinary tract infection, constipation, and respiratory problems also are frequent.

Complications from drug therapy for osteoporosis include the following: potential increase in breast cancer (estrogen), heart disease (estrogen), clotting and thromboembolic problems (estrogen, raloxifene), and endometrial cancer (in those using only estrogen); hot flashes (raloxifene); upper gastrointestinal symptoms and esophagitis from oral alendronate, risedronate, and ibandronate; fever, muscle and joint aches, and influenza-like symptoms from intravenous ibandronate and zoledronic acid; osteonecrosis of the jaw and atypical femur fractures with long-term bisphosphonates; running nose and headache from calcitonin; and transient mild hypercalcemia with teriparatide and a small increase in infections with denosumab.

G23.1 Progressive supranuclear palsy
G90.3 Multi-system degeneration of the autonomic nervous system
G31.85 Corticobasal degeneration

Definition

Parkinson disease (PD) is a chronic, progressive neurodegenerative disease. On pathologic examination, it is characterized by preferential degeneration of dopaminergic neurons in the substantia nigra pars compacta and the presence of cytoplasmic inclusions known as Lewy bodies. It is characterized clinically by a resting tremor, bradykinesia, and rigidity. It is important to distinguish PD from the disorders that are known collectively as the Parkinson-plus syndromes. These are relatively rare disorders that share some of the features of PD, such as rigidity and bradykinesia. However, the Parkinson-plus syndromes do not respond to medical treatment and have some unique clinical features as well.

The prevalence of PD has been estimated in more than 80 studies conducted around the world. The most consistent finding is that PD is an age-related disease. Between the ages of 50 and 59 years, the prevalence is estimated at 273 per 100,000, whereas between 70 and 79 years, the prevalence is estimated at 2700 per 100,000 [1]. Some studies have reported a higher prevalence of PD in men, whereas other studies have not.

The genetic contribution to the development of PD is an area of intense study. A variety of gene mutations that can cause PD have been identified in family studies [1]. However, their contribution to the development of PD in a larger population is not yet fully appreciated. Environmental risk factors are also thought to play a role in the pathogenesis of PD. Numerous studies have focused on the risk of pesticide and heavy metal exposure to the development of PD. Whereas the methodology varies in different studies, in those with an occupational exposure to pesticides or heavy metals, the data have been mixed, indicating either an increased risk for development of PD or no increased risk [1].

Symptoms

The most common initial manifestations of PD are rest tremor and bradykinesia. The resting tremor is suppressed by either purposeful movement or sleep and exacerbated by anxiety. The bradykinesia may produce a sensation of stiffness in the affected arm or leg. Pain is also a part of PD. An aching pain in the initially affected limb may first be attributed to bursitis or arthritis. Less common presenting complaints include gait difficulty and fatigue. It is not uncommon for one of these features to be present for months or even years before others develop.

As the disease progresses, there is marked difficulty in both initiating and terminating movement. There is difficulty in rising from a seated position, particularly when one is seated in a sofa or chair without armrests. Handwriting becomes smaller and more difficult to read. Friends and family members often complain that the patient's speech is more difficult to understand, particularly on the telephone. The symptom of a softer voice with a decline in enunciation is known as hypophonia.

Physical Examination

The most distinctive clinical feature is the rest tremor. It is typically present in a single upper extremity early in the course of the disease. As the disease progresses, the resting tremor may spread to both the ipsilateral lower limb and

the contralateral limbs. Examination of motor tone reveals cogwheel rigidity in the affected limb. Motor strength, however, remains unaffected.

Additional features that must be evaluated in an examination include rapid, repetitive limb movements and gait. Examination of repetitive movements of the fingers or entire hand will reveal bradykinesia and decreased amplitude and accuracy of finger tapping or toe tapping movements in the affected limb. Examination of gait will reveal decreased arm swing on the affected side, smaller steps, and an inability to pivot turn. Typically, patients make several steps to complete a turn because of some degree of postural instability. Deep tendon reflexes and sensation are not affected in PD.

In advanced PD, loss of postural reflexes becomes evident. Individuals are unable to maintain balance when turning. Other manifestations of advanced PD include freezing episodes and dysphagia. There is also a spectrum of cognitive impairment in PD, extending from minimal cognitive impairment to PD with dementia. Minimal cognitive impairment is defined as a gradual decline in cognitive function, identified by the patient or caregiver, that does not interfere significantly with functional independence [2]. PD with dementia is dementia with a slowly progressive course of cognitive impairment that most prominently affects attention, executive, and visuospatial functions [3].

In examination of someone who is taking medication for PD, it is important to record the time at which the last dose of medication was taken relative to the time at which the examination occurs. Medications for PD are particularly good at ameliorating the rest tremor and bradykinesia, particularly in the early stages of the disease. Typically, the rest tremor will subside for 1 to 3 hours after the last dose of medication. Other features, such as reduced arm swing, hypophonia, and loss of postural reflexes, do not respond to oral medication.

Functional Limitations

Functional limitations depend on which symptoms are most prominent in a particular patient. Early in the course of PD, the sole limitation may be in one's ability to write legibly. Affected individuals are still able to perform activities of daily living, although they may prefer to use the unaffected limb for tasks such as shaving and dressing. Although the rest tremor may result in a feeling of self-consciousness or embarrassment, it does not affect one's independence as it is suppressed with purposeful movement.

As the disease progresses, the ability to perform fine motor skills declines, and difficulty with standing and gait develops. An individual will have difficulty in buttoning a shirt or tying shoelaces. More time will be required to stand and to initiate gait. Postural instability with a tendency to retropulse also develops. Thus patients have difficulty in climbing stairs and walking safely and quickly. Slowed reaction times may also affect one's ability to drive safely. Decisions about whether someone should drive are often difficult and must be made on an individual basis. Marked hypophonia may make speaking on the telephone difficult as well. As the voice becomes more affected, dysphagia is likely to develop.

One aspect of PD that has historically received little attention is the effect it has on sexual activity. Men may experience erectile dysfunction and difficulty with ejaculation as part of the autonomic dysfunction found in PD. Women may experience inadequate lubrication and a tendency to urinate during sex secondary to autonomic dysfunction. In both genders, hypersexuality may be seen as a side effect of treatment with dopamine agonists [4].

In end-stage PD, limitations include marked dysphagia and severe abnormalities of gait that require both devices and one or two persons for assistance. At this stage, help is necessary for all activities of daily living as well.

Diagnostic Studies

PD is a clinical diagnosis. Conventional laboratory investigations do not contribute to the diagnosis or management of PD. Computed tomography and magnetic resonance imaging scans of the brain do not reveal any consistent abnormalities. A dopamine transporter radioligand has recently become available for clinical use, in single-photon emission computed tomography scanning, to assist in the evaluation of those with suspected PD. The scan is known as a DaTscan, and a recent analysis demonstrates that it does not provide greater accuracy than a clinical diagnosis based on history and examination of a patient [5].

Differential Diagnosis

The differential diagnosis includes essential tremor and several diseases known collectively as the Parkinson-plus syndromes: Lewy body dementia, progressive supranuclear palsy, multiple system atrophy, and corticobasal degeneration.

Essential tremor	An involuntary, rhythmic tremor of a body part, most commonly affecting arms and hands but that can also involve head, voice, tongue, trunk, or legs
Lewy body dementia	Motor symptoms of Parkinson disease with rapidly progressive dementia within the first year; visual hallucinations are common
Progressive supranuclear palsy	Bradykinesia, rigidity, frequent falls early in disease course, rest tremor, and inability to voluntarily move the eyes upward
Multiple system atrophy	Bradykinesia, rigidity, ataxia, and autonomic dysfunction (flushing, palpitations, nausea, vomiting)
Corticobasal degeneration	Bradykinesia, rigidity, inability to coordinate purposeful movements (apraxia), and sense that limbs are not one's own (alien limb syndrome)

Treatment

Initial

The decision to initiate medical treatment is based on the degree of disability and discomfort that the patient is experiencing. Six classes of drugs are used to treat PD (summarized in Table 141.1). The selection of a particular drug

Table 141.1 Classes of Antiparkinson Medications, Mechanisms of Action, Beneficial Effects, and Side Effects

Drug Class	Specific Agents	Mechanism of Action	Effective for	Side Effects
Anticholinergic	Benzotropine	Muscarinic receptor blocker	Tremor, rigidity	Dry mouth, blurred vision, constipation, urinary retention, confusion, hallucinations, impaired concentration
Antiviral	Amantadine	Promotes synthesis and release of dopamine	Tremor, rigidity, akinesia	Leg edema, livedo reticularis, confusion, hallucinations
Dopamine replacement	Levodopa	Converted to dopamine	Tremor, rigidity, akinesia, freezing	Nausea, diarrhea, confusion, hallucinations
Dopamine agonists (D ₁ and D ₂)	Bromocriptine, pergolide	Dopamine analogues that bind to D ₁ and D ₂ receptors	Rigidity, akinesia	Leg edema, nausea, confusion, hallucinations
Dopamine agonists (D ₂)	Ropinirole, pramipexole	Dopamine analogues that bind to D ₂ receptors	Rigidity, akinesia	Leg edema, sleep attacks, nausea, confusion, hallucinations
Monoamine oxidase B inhibitors	Selegiline, rasagiline	Inhibit the metabolism of dopamine	Mild reduction in "wearing off" from levodopa	Nausea, hallucinations, confusion
Catechol O-methyltransferase inhibitor	Entacapone	Inhibits the metabolism of dopamine	Mild reduction in "wearing off" from levodopa	Dyskinesia, nausea, diarrhea

depends on the patient's main complaint, which is usually either a rest tremor or bradykinesia. There is no evidence to suggest that expediting or delaying the onset of treatment for PD has any effect on the overall course of the disease. However, it is clear that those who do not receive treatment and are bradykinetic are at greater risk of falling and injuring themselves.

Anticholinergic agents are the oldest class of medications used in PD. They are most effective in reducing the rest tremor and rigidity associated with PD. However, the side effects associated with anticholinergic agents typically limit their usefulness. Amantadine is also used in the treatment of PD. Amantadine produces a limited improvement in akinesia, rigidity, and tremor.

Dopamine replacement remains the cornerstone of antiparkinson therapy. Levodopa is the natural precursor to dopamine and is converted to dopamine by the enzyme aromatic amino acid decarboxylase. To ensure that adequate levels of levodopa reach the central nervous system, levodopa is administered simultaneously with a peripheral decarboxylase inhibitor. In the United States, the most commonly used peripheral decarboxylase inhibitor is carbidopa. Levodopa is most effective in reducing tremor, rigidity, and akinesia. The most common side effects, seen with the onset of treatment, are nausea, abdominal cramping, and diarrhea. Long-term treatment with levodopa is associated with three types of complications: hourly fluctuations in motor state, dyskinesias, and a variety of psychiatric complaints including hallucinations and confusion. However, it is not clear whether the motor fluctuations are due to the levodopa treatment alone, the disease progression alone, or a complex interplay of imperfect dopamine replacement and the inexorable progression of disease. In summary, current evidence supports the use of dopamine

replacement as soon as the symptoms of PD become troublesome to the individual patient. There is no evidence that supports withholding of treatment to minimize long-term motor complications.

Dopamine agonists, which directly stimulate dopamine receptors, are also used in the treatment of PD. These agents can be used either as an adjunct to levodopa therapy or as monotherapy. The older dopamine agonists, which are relatively nonspecific and exert their effects at both D₁ and D₂ receptors, are bromocriptine and pergolide. In comparison to the side effects seen with levodopa, there is a lower frequency of dyskinesias and a higher frequency of confusion and hallucinations. The newer dopamine agonists pramipexole and ropinirole are more specific for D₂ receptors. These newer agents have been reported to cause daytime somnolence, peripheral edema, and impulse control disorders [6]. All dopamine agonists can cause orthostatic hypotension, particularly when they are first introduced. It is best to start with a small dose of medication at bedtime and then slowly increase the total daily dose.

Inhibitors of dopamine metabolism are also used in the medical treatment of PD. Both selegiline and rasagiline inhibit monoamine oxidase B, which metabolizes dopamine in the central nervous system. Thus, inhibitors of monoamine oxidase B are thought to improve an individual's response to levodopa by alleviating the motor fluctuations that are seen with long-term levodopa treatment. Another agent that inhibits the metabolism of dopamine is entacapone. Entacapone inhibits catechol O-methyltransferase in the periphery. Entacapone is administered in conjunction with levodopa and, by inhibiting peripheral catechol O-methyltransferase activity, increases the amount of levodopa that reaches the central nervous system. The benefits

of entacapone treatment include a reduction in total daily levodopa dose and an improvement in the length of time of maximum mobility [7].

Rehabilitation

The clinical pathologic process seen in PD reveals that patients tend to become more passive, less active, and less motivated as the disease progresses. The benefits to physical and occupational therapy are thus more far reaching than a simple improvement in motor function. The physical benefits include improvement in muscle strength and tone as well as maintenance of an adequate range of motion in the joints. The psychological benefits include enlistment of the patient as an active participant in treatment and provision of a sense of mastery over the effects of PD. Both physical therapy and occupational therapy focus on mobility, the use of adaptive equipment, and safety in both the home and community.

Because the symptoms of PD gradually worsen over time, individuals can benefit from periodic physical therapy training throughout the course of their illness. The training may take place through either community-based programs that are more readily accessible for those who live far from an academic center or home-based programs for those who cannot easily travel. An emphasis on gait training is particularly helpful to prevent falls and injury. Gait training typically involves training an individual to be conscious of taking a longer stride and putting the foot down with each step. Another method is to use visual cues to maintain a regular size for each step. For example, one can put strips of masking tape on the floor, at a regular interval that is comfortable for one's height, weight, and gender. As PD progresses, episodes of frozen gait, in which the feet seem to be stuck to the floor, occur. Freezing episodes can be broken by multiple techniques, such as visualizing that one is stepping over an imaginary line on the floor, counting in a rhythmic cadence, or marching in place.

Occupational therapy is particularly helpful in recommending adaptive devices or establishing new routines that allow people with PD to continue to live independently. For example, the use of a long-handled shoehorn eliminates the need to bend over and thus reduces the risk that a person with PD will fall while getting dressed. Other examples of adaptive equipment are a firmly secured grab bar in the bathtub and a relatively high toilet seat with armrests to minimize the risk of freezing while on the toilet.

Speech therapy plays a critical role for those PD patients who suffer from communication difficulties. Although dysarthria is difficult to treat, hypophonia can be overcome with training. Specifically, the Lee Silverman Voice Treatment program has been shown to be effective in improving both the volume and clarity of speech in those with PD [8]. Swallow evaluation and therapy are also helpful in the treatment of dysphagia, which occurs as PD progresses.

Procedures

Feeding tubes are sometimes used in individuals who have severe end-stage PD. Some patients choose hospice care, without artificial feeding at that point. Individuals who do get feeding tubes may need to have medication doses

adjusted (e.g., carbidopa/levodopa will now bypass the esophagus and have a shortened time to onset of action).

Surgery

Although a large number of medications are available for the treatment of early and moderately advanced PD, they are of limited efficacy in those with advanced PD. Several surgical procedures are currently available for those with advanced PD. These procedures consist of either creation of a permanent lesion or insertion of an electrical stimulator in a specific nucleus of the brain.

Thalamotomy consists of introduction of a lesion in the ventral intermediate nucleus of the thalamus. Thalamotomy has been reported to produce a reduction in tremor of the contralateral limb in 85% of the patients who were treated. Thalamotomy is recommended in PD patients with an asymmetric, severe, medically intractable tremor.

Unilateral pallidotomy consists of introduction of a lesion in the globus pallidus. The most striking benefits are a reduction in contralateral drug-induced dyskinesias, contralateral tremor, bradykinesia, and rigidity. Unilateral pallidotomy is recommended in PD patients with bradykinesia, rigidity, and tremor who experience significant drug-induced dyskinesia despite optimal medical therapy. However, data regarding the long-term cognitive effects of unilateral pallidotomy are limited and varied in their findings [9,10]. Thus neuropsychological evaluation is recommended in all patients both before and after surgery.

Deep brain stimulation (DBS) for PD consists of high-frequency electrical stimulation in either the globus pallidus or the subthalamic nucleus. DBS requires surgery, in which the source of electrical stimulation is placed subcutaneously in the chest wall and the leads to which it is attached are placed in one of the locations listed. The advantage of DBS is that the degree of electrical stimulation can be easily adjusted, externally, once the DBS unit is in place. In contrast, both thalamotomy and pallidotomy result in permanent, fixed lesions in the brain. DBS of the ventral intermediate nucleus of the thalamus is effective in the treatment of a severe and disabling tremor that is unresponsive to medical therapy, with reports of approximately 80% improvement in tremor 5 years after DBS implantation [11]. DBS of the globus pallidus results in a marked reduction in dyskinesia. There are also improvements in bradykinesia, speech, gait, rigidity, and tremor. DBS of the subthalamic nucleus also results in marked improvement in tremor, akinesia, gait, and postural stability [12].

Potential Disease Complications

Depression is found in approximately 35% of those with PD [13]. It may be difficult to distinguish true depression from the apathy associated with PD. The crucial factor is to determine whether the patient has a true disturbance of mood, with loss of interest, sleep disturbance, and sometimes suicidal thoughts. The reasons for depression in PD are a subject of debate. There is a suspicion that the pathologic process of PD itself may predispose to depression. Regardless of the cause, recognition and treatment of depression may have a significant impact on the overall disability caused by the illness. Many PD patients have been

treated safely and effectively with selective serotonin reuptake inhibitors, such as fluoxetine and paroxetine. Tricyclic antidepressants can be used, although their anticholinergic properties may limit their effectiveness.

Gastrointestinal complications also occur in PD. Dysphagia is typically due to poor control of the muscles of both mastication and the oropharynx. Soft food is easier to eat, and antiparkinson medication improves swallowing. Constipation is a frequent complaint in those with PD. Treatment includes increase in physical activity; discontinuation of anticholinergic drugs; and maintenance of a diet with intake of adequate fluids, fruit, vegetables, fiber, and lactulose (10 to 20g daily).

Potential Treatment Complications

The motor complications seen with pharmacologic treatment are divided into two categories: fluctuations (off state) and levodopa-induced dyskinesias. The off state consists of a return of the signs and symptoms of PD: bradykinesia, tremor, and rigidity. Patients may also experience anxiety, dysphoria, or panic during an off state.

The development of levodopa-induced dyskinesias appears to be related to the degree of dopamine receptor supersensitivity. As PD progresses, there is an increasing loss of dopamine receptors. This results in an increased sensitivity of the remaining dopamine receptors to dopamine itself. Thus, there is a greater chance for development of dyskinesias at a given dose of levodopa. Treatment options are to lower each dose of levodopa but with an increase in the frequency with which it is taken; to add or to increase the dose of a dopamine agonist while the dose of levodopa is decreased; and to add amantadine, which has been shown to be an antidyskinetic agent in some patients [14]. There are potential complications to each of these solutions: reducing each dose of levodopa while increasing the frequency of doses (e.g., once every 2 hours) is a difficult schedule for a patient to maintain; adding or increasing the dose of dopamine agonist may result in compulsive behaviors (shopping, gambling, hypersexuality), excessive daytime sleepiness, and peripheral edema; and amantadine may cause

confusion. An alternative is to treat those who continue to experience an improvement in their mobility with levodopa but develop dyskinesias that become more pronounced as the day progresses with DBS.

Definition

Peripheral neuropathies are a collection of disorders characterized by the generalized dysfunction of peripheral nerves. This group of diseases is heterogeneous, including those that predominantly affect the nerve axon, others that primarily affect the myelin sheath, and still others that involve both parts of the nerve simultaneously. In addition, some peripheral neuropathies affect only small, unmyelinated fibers, whereas others predominantly involve only large myelinated ones. [Table 142.1](#) contains a list of the most frequently encountered forms of peripheral neuropathy.

Peripheral neuropathy is common; one Italian study suggested a prevalence of about 3.5% in the general population [1]. In diabetes, one study demonstrated clinical peripheral neuropathy affecting 8.3% of individuals compared with a control population, in whom 2.1% of individuals were affected [2]. After 10 years, 41.9% of the diabetic patients had peripheral neuropathy compared with 6% of the control subjects.

Defining peripheral neuropathy remains no simple task. Members of the American Academy of Neurology along with those of the American Association of Electrodiagnostic Medicine and the American Academy of Physical Medicine and Rehabilitation have developed a formal case definition for distal symmetric polyneuropathy (the most common form) [3]. The authors chose to use a combination of symptoms, signs, and electrodiagnostic testing results to formulate an ordinal ranking system to identify the likelihood of the disease in a given patient. Although it is a useful tool for future research studies, the necessity of applying such a complex approach underscores the difficulty in attempting to define peripheral neuropathy in any simple fashion.

Symptoms

Patients with peripheral neuropathy present with a number of specific sensory complaints, including decreased sensation often associated with pain, tingling (paresthesias), and burning. They may complain of a “sock-like” feeling in the feet or that the feet are persistently cold. Some patients, usually with more advanced disease, will note atrophy of the intrinsic foot muscles and some weakness, especially with the development of partial footdrop. Walking difficulties usually also develop once sensation is significantly

impaired. Sensory symptoms in the hand (paresthesias and reduced tactile sensation) usually develop once an axonal peripheral neuropathy has progressed up to about the level of the knees. In patients with generalized demyelinating peripheral neuropathies, more generalized symptoms of weakness and sensory loss are often present, although distally predominant paresthesias often occur. The history includes a detailed past medical history, review of systems, and any prior exposure to toxins (Table 142.2).

Physical Examination

The physical examination demonstrates distinct abnormalities that depend on the form of peripheral neuropathy present. Most commonly, patients present with a sensorimotor axonal peripheral neuropathy. In this condition, decreased sensation to pinprick, vibration, light touch, and temperature may be identified distally in the lower extremities with normal sensation more proximally. Of note, vibration sensation testing with a tuning fork has been shown to be reliable [4]. Some weakness of toe or foot extension and flexion may also be apparent. Deep tendon reflexes will be hypoactive distally (e.g., ankle jerks decreased relative to knee jerks).

In patients with acquired demyelinating peripheral neuropathy, the examination may demonstrate marked generalized weakness with some abnormal sensory findings, usually including decreased joint position sense. In this disorder, deep tendon reflexes may be reduced or diffusely absent. Patients with hereditary demyelinating polyneuropathies may demonstrate distal muscle atrophy in the feet and lower legs. Such patients may develop a pes cavus foot deformity, in which the foot is foreshortened and has a very high arch. A “champagne bottle” appearance to the legs (where muscle atrophy of the lower leg, especially of the

calf, is prominent) may also be present. As any peripheral neuropathy progresses, lower extremity sensory loss may lead to gait unsteadiness, and upper extremity sensory loss may produce decreased hand dexterity.

Functional Limitations

Patients with peripheral neuropathy face a number of potential functional limitations. In those individuals with a distal axonal peripheral neuropathy, limitations usually include problems with gait and unsteadiness, especially as the neuropathy progresses. If pain is a prominent symptom, the activities of daily living may be compromised to some extent. Pain may also be prominent at night, interfering with sleep. In those patients with very advanced axonal peripheral neuropathy or demyelinating forms, such as hereditary Charcot-Marie-Tooth disease, weakness can produce major functional limitations, restricting the patient's walking ability and in some cases leading to dyspnea and nocturnal hypoventilation. In patients with some chronic forms of demyelinating polyneuropathy, weakness of both proximal and distal muscles can become severe, limiting the performance of many activities of daily living. Sensory deficits can limit one's ability to button shirts, to zip pants, to turn a key in a lock, to tie shoelaces, or to type on a computer.

Diagnostic Studies

Electrodiagnostic studies (including electromyography and nerve conduction studies) remain the most important first tests in the evaluation of polyneuropathy [5]. Nerve conduction studies assist in determination of whether the peripheral neuropathy is mainly demyelinating, axonal, or mixed (Figs. 142.1 and 142.2) by evaluation of the amplitude and conduction velocities of the motor and sensory responses obtained [6]. In axonal neuropathies, amplitudes are reduced and conduction velocities are relatively normal; in demyelinating neuropathies, amplitudes are generally preserved but conduction velocities are decreased; in mixed neuropathies, a combination of reduced amplitude and conduction velocities is present. In small-fiber neuropathies, nerve conduction studies are generally normal. Likewise, nerve conduction studies help determine the severity of the process as well. Although needle electromyography plays a more limited role in the diagnosis of peripheral neuropathy, a gradient of reinnervation, in which distal muscles are most abnormal and proximal muscles less affected, helps determine the degree of motor involvement. In addition, needle electromyography may assist in determining whether a superimposed problem, such as polyradiculopathy, is also contributing.

In general, a number of serologic tests are also performed to identify the cause of the peripheral neuropathy. These are outlined in Table 142.3.

Additional workup is occasionally necessary. Sural nerve biopsy can be useful for determining the cause of the polyneuropathy for some conditions that are difficult to diagnose, such as amyloid neuropathy, as well as some other unusual forms of peripheral neuropathy. The analysis of cutaneous sensory fibers through the use of skin biopsy to identify the presence of peripheral neuropathy involving only small, unmyelinated fibers is now also routinely performed to assist with the diagnosis of idiopathic small-fiber neuropathy or that associated with certain conditions, such as amyloid [7]. On occasion, muscle

FIGURE 142.2 Schematic representation of a motor nerve extending from a cell body to the muscle it innervates.

Table 142.3 Serologic Testing in Peripheral Neuropathy

Baseline Testing

Vitamin B₁₂
Thyroid-stimulating hormone
Rapid plasma reagin (or VDRL test)
Serum glucose
Serum hemoglobin A_{1c}
Antinuclear antibody
Erythrocyte sedimentation rate
Serum protein electrophoresis
Urine protein electrophoresis

Some Additional Tests, Depending on Clinical Suspicion

Serum protein immunophoresis
24-Hour urine collection for heavy metals
24-Hour urine collection for porphyrins
Glucose tolerance testing
Human immunodeficiency virus infection testing
Anti-Ro, anti-La antibodies (Sjögren syndrome)
Anti-Hu antibody (paraneoplastic neuropathy)
Additional antibody testing in certain demyelinating disorders
Antimyelin-associated glycoprotein
Genetic testing (for disorders such as familial amyloidosis, Charcot-Marie-Tooth disease)

FIGURE 142.1 Types of peripheral nerve damage.

biopsy may be helpful in this regard as well because vasculitic abnormalities or amyloid can also be identified in skeletal muscle. Lumbar puncture may aid in the determination of whether an acquired demyelinating peripheral neuropathy is present by the identification of a very elevated cerebrospinal fluid protein concentration in the presence of a normal number of white cells (so-called albuminocytologic dissociation). Autonomic testing, such as quantitative sudomotor axon reflex testing, tilt-table testing, and heart rate variability to deep breathing, can also be helpful in delineating the involvement of the autonomic nervous system in the neuropathic process [8].

Differential Diagnosis

Myelopathy (spinal cord compression)
Lumbosacral polyradiculopathy (lumbar stenosis)
Mononeuropathy multiplex

Treatment

Initial

If a cause of the axonal peripheral neuropathy is known or identified (which generally is achieved about 80% of the time), treatment geared toward the underlying disorder itself might help slow progression of the polyneuropathy. For example, improved glucose control can help improve neuronal function in diabetic neuropathy [9]. Likewise, in those people with a neuropathy secondary to toxin exposure, such as alcoholic neuropathy, decreased exposure to the toxin may be helpful.

In patients with axonal peripheral neuropathies, treatment is usually symptom based, with efforts toward reducing pain and dysesthesias. A number of drugs have proved useful in this regard [10]. The tricyclic antidepressants remain most effective (generally nortriptyline or amitriptyline, starting with 10 mg at bedtime and increasing as needed until improvement occurs). Gabapentin (starting at a dose of 100 to 300 mg three times daily) has also gained wide acceptance in the treatment of this disorder during the past several years [11]. Two newer drugs specifically approved for use in diabetic polyneuropathy, duloxetine (Cymbalta), at 30 mg or 60 mg daily, and pregabalin (Lyrica) at a dose of 50 mg three times daily, increasing to 100 mg three times daily if needed, can be useful in a variety of peripheral neuropathies [12,13]. However, it is not clear that either of these is more efficacious than previously available and more inexpensive medications [14]. In patients in whom these measures prove of limited value, the use of long-acting narcotic agents may occasionally be necessary. In patients with certain forms of demyelinating peripheral neuropathy (such as chronic inflammatory demyelinating polyradiculoneuropathy), immunosuppressive or immunomodulating therapies can make a dramatic difference in the patient's symptoms and level of function. Drugs including corticosteroids, azathioprine, cyclosporine, and cyclophosphamide can be used [15]. Intravenous immune globulin and plasmapheresis are also widely used in this group of disorders [16,17]. Finally, in all patients with distal sensory loss due to peripheral neuropathy, and especially in those with diabetic peripheral neuropathy, regular podiatric care is extremely important in preventing the development of serious foot complications, such as ulcerations [18].

Rehabilitation

Physical therapy may be recommended to improve mobility, muscle strength, and balance. In patients with moderate to severe peripheral neuropathy, gait training may consist of balance exercise and use of an assistive device, such as a cane or walker. Either a physical or occupational therapist can review falls precautions (e.g., avoiding throw rugs in the home, using a chair in the bath or shower). Some patients may benefit from an ankle-foot orthosis. However, in patients with compromised sensation, monitoring of the skin to prevent breakdown when a brace is used is critical. Patients can be taught to self-monitor their skin with use of a long-handled mirror to check the bottom of their feet. Custom shoes (e.g., extra depth and width) may be beneficial, as can custom shoe orthoses.

In patients with more advanced peripheral neuropathy, evaluation by an occupational therapist may help maximize the function of the hands and arms. The occupational therapist can provide the patient with information about adaptive equipment, such as elastic shoelaces, wide grip handles for cookware and utensils, and shoehorns. An occupational or physical therapist experienced in assistive technology can also be helpful in specialized equipment, such as voice-activated computer software, driving adaptations, and environmental control units.

If pain is an issue, therapeutic modalities may be used to alleviate the pain. These may include instruction on use of transcutaneous electrical nerve stimulation, paraffin baths, and the like. It is important to caution the patient with impaired sensation not to use any heat or ice that may cause burns or frostbite. Individuals with impaired vascular status also should be advised not to use ice because of its vasoconstrictive effects.

Procedures

Patients with peripheral neuropathy are generally at increased risk for development of superimposed compressive neuropathies, such as carpal tunnel syndrome, that can be challenging to diagnose [19]. Treatment with local corticosteroid injections can be helpful for this problem (see Chapter 36).

Surgery

Surgery may be necessary for some associated conditions, including severe carpal tunnel syndrome, but it is usually more relevant to patients who develop infections of the distal lower extremities and require amputations. Other, less severe distal leg problems may also develop, requiring orthopedic or podiatric surgery. Although lower extremity nerve release surgeries are sometimes performed in the hope of treating neuropathic symptoms [20], there is little evidence to support the use of these procedures to treat peripheral neuropathy [21].

Potential Disease Complications

A number of potential foot complications can occur, including persistent, intractable pain, skin ulcerations, and foot trauma, possibly leading to amputations. Serious trauma secondary to increased gait unsteadiness is another potential problem. Finally, depression due to immobility and persistent pain also often plays a role in patients with more advanced peripheral neuropathy.

Potential Treatment Complications

The tricyclic antidepressants and other pain medications have the potential side effect of drowsiness. Dry mouth, constipation, and urinary retention also occur commonly with the tricyclic antidepressants. Side effects of duloxetine include dizziness, nausea, and constipation. Side effects of pregabalin include dizziness and somnolence. Addiction remains a major concern with narcotic use.

Treatment of the autoimmune peripheral neuropathies poses significant risk, given the inherent toxicity of the medications employed. Patients using immunosuppressive medications are at increased risk for infection, malignant neoplasia, anemia, and multiple other side effects (e.g., liver toxicity with azathioprine, renal failure with intravenous immune globulin, hemorrhagic cystitis with cyclophosphamide).

Skin breakdown can occur with improper bracing.

Definition

Brachial plexopathy is the pathologic dysfunction of the brachial plexus, a complex peripheral nerve structure in the proximal upper extremity. The brachial plexus starts just outside the spinal cord in the lower neck and extends to the axilla. The total average brachial plexus length is approximately 6 inches [1]. The plexus is divided into five sections: roots, trunks, divisions, cords, and branches or terminal nerves. The spinal nerves C5 through T1 classically supply anterior primary rami of the nerve roots, which then form the plexus. Variations in nerve root supply that involve other nerve roots are said to be expanded. When the C4 nerve root also supplies the brachial plexus and T1 contribution is minimal, the plexus is called prefixed. When the T2 nerve root supplies the brachial plexus and C5 contribution is minimal, the plexus is said to be postfixed [2]. The nerve roots combine to form the trunks behind the clavicle. There are three trunks, the upper, middle, and lower. The upper is formed from the C5 and C6 nerve roots, the middle is a continuation of C7, and the lower is formed from C8 and T1. The trunks then divide behind the clavicle into anterior and posterior divisions. Just inferior to the clavicle, the divisions coalesce into cords. The cords travel along the axillary artery, just inferior to the clavicle, and are named for their spatial relationship to the artery. The posterior cord is formed from the union of the three posterior divisions. The lateral cord is formed by the union of the anterior divisions of the upper and middle trunks. The medial cord is the continuation of the anterior division of the lower trunk. Nerve branches are the most distal elements of the brachial plexus and are the major nerves of the upper extremity. These branches begin in the distal axilla and other than the median nerve, which is formed by contributions from the medial and lateral cords, are continuations

of the cords. There are also numerous peripheral nerves that arise directly from the roots, trunks, and cords (Fig. 143.1).

Brachial plexopathy can be due to wide-ranging causes, including idiopathic, iatrogenic, autoimmune, traumatic, neoplastic, and hereditary. It can occur in any age group; but other than when it is secondary to obstetric trauma, it usually occurs from the ages of 30 to 70 years. Men are affected two to three times as often as are women, and the reason is likely due to their more frequent participation in vigorous athletic activities that can lead to trauma. About half of the cases have no identified precipitating event; in others, brachial plexopathy follows an antecedent infection, trauma, surgery, or immunization.

Symptoms

Brachial plexopathy can result in symptoms of pain, weakness, and numbness, both at the level of the brachial plexus

and distally in the supplied upper extremity. The area of pain and other symptoms correlates with the portion of the brachial plexus involved and the specific nerve elements from that area. Depending on the cause of the plexopathy, symptom onset can range from sudden to insidious. Because of the complex muscle suspension of the shoulder joint, chronic brachial plexopathy may result in glenohumeral subluxation and instability due to stretching of the shoulder capsule. Brachial plexopathy usually does not cause prominent neck pain. Some brachial plexopathies may occur bilaterally and therefore cause symptoms in both upper extremities.

Physical Examination

The physical examination of the brachial plexus for brachial plexopathy must be thorough because of the complexity of its structure and function. The shoulder girdle and

FIGURE 143.1 The brachial plexus. The clinician must be able to visualize this structure in performing electrodiagnostic examination so that an appropriate number of muscles and nerves are sampled to localize a lesion. (From Dumitru D, Amato A, Zwarts M. *Electrodiagnostic Medicine*, 2nd ed. Philadelphia, Hanley & Belfus, 2002.)

entire extremity need to be exposed during examination to allow close inspection of muscle bulk and fasciculations. Assessment of atrophy of muscles is often assisted by side-to-side comparisons. Muscle strength examination needs to be thorough and to include proximal muscles not commonly tested, such as infraspinatus, supraspinatus, rhomboids, and serratus anterior. Sensory testing also must be thorough, with both dermatomal and peripheral nerve sensory distributions examined. A musculoskeletal examination of the shoulder joint is helpful; joint disease can be both a possible primary cause of pain and a secondary effect of plexopathy. Shoulder range of motion and signs of tendinosis as well as reflexes and any muscle atrophy need to be assessed. The lack of pain exacerbation with neck movement and multi-root distribution of sensory or motor deficits can help distinguish brachial plexopathy from cervical radiculopathy, which more commonly affects a single root [3]. It is often not possible to determine the exact location of a brachial plexus lesion from physical examination, but the examination is usually helpful in focusing electrodiagnostic and radiologic testing.

Functional Limitations

Depending on whether the brachial plexopathy involves the upper plexus, lower plexus, or entire plexus, the proximal shoulder muscles, the distal muscles involved in fine finger movements, or the entire extremity can be weak or numb. Activities of daily living, such as dressing, feeding, and grooming, can be significantly affected. These impairments can result in disabilities in many activities, including computer use, writing, and driving. Brachial plexopathy secondary to birth trauma may subsequently cause difficulty for children and teens with sports and other recreational activity.

Diagnostic Studies

Electromyography (EMG) can be helpful in localizing the pathologic area in brachial plexopathy as well as in determining the severity of axonal injury and the potential for recovery. However, many brachial plexopathies cannot be definitely localized by EMG because of subtle findings encountered with incomplete nerve injury and the complexity of plexus-related innervation. The nerve conduction and needle EMG assessment is best directed by both symptoms and physical examination findings. Both nerve conduction studies and needle EMG are required for complete assessment. Sensory nerve conduction studies can help in localization by the pattern of abnormalities seen and in judging injury severity based on reductions of amplitudes or absence of potentials. The nerve conduction study may not detect abnormality if the lesion is mild in severity or too recent to allow axonal degeneration.

The following five basic sensory nerve conduction studies are suggested as a screen for brachial plexus evaluation: lateral antebrachial cutaneous, median recording from the thumb, median recording from the index finger, superficial radial, and ulnar recording from the little finger [2]. The presence of fibrillation potentials in EMG is particularly sensitive for motor axon loss and helps localize the site of lesions. The choice of muscles sampled on EMG is usually

focused on the area of interest, but other areas are also included for the exclusion of wider disease. It is important to include paraspinal muscles of the relevant areas to investigate the possibility of radiculopathy (paraspinals are supplied by the posterior primary rami of the nerve roots, which do not supply the brachial plexus). EMG evaluation of the brachial plexus is complex and best performed by experienced electromyographers.

Radiologic studies of the plexus are helpful to evaluate the severity of trauma, presence of mass lesions, and inflammation of the brachial plexus nerve elements [4]. Magnetic resonance imaging (MRI) has become the study of choice in evaluation of traumatic brachial plexus injuries [5]. More than 80% of traumatic nerve root avulsions will show pseudomeningoceles, which are tears in the meningeal sheath surrounding the nerve roots that allow extravasation of cerebrospinal fluid into nearby tissues. They appear bright on T2-weighted images. MRI is also the most useful study for evaluation of other causes of brachial plexopathy, such as tumors, both secondary and primary [6]. An early MRI sign in Pancoast tumor is obliteration of the interscalene fat pad, which is best visualized on coronal T1-weighted MRI [7]. Inflammatory changes in the brachial plexus may be visualized with MRI, including brachial neuralgic amyotrophy [8].

Computed tomography myelography is increasingly becoming the study of choice in the preoperative evaluation of infants with obstetric brachial plexopathy, given its usefulness in identifying nerve root avulsion, which affects operative interventions [9,10].

Musculoskeletal ultrasonography has been used in the evaluation of suspected neoplastic brachial plexopathy. Sonography may identify the neoplastic lesion as a hypoechoic mass or present evidence consistent with a compressive lesion, such as segmental neuronal swelling of the involved portion of the brachial plexus [11].

Chest radiographs are valuable for the evaluation of diaphragmatic paralysis in traumatic brachial plexopathy, which usually indicates an irreparable lesion of the brachial plexus [12].

Differential Diagnosis

- Generalized peripheral neuropathy
- Focal peripheral neuropathy
- Cervical radiculopathy
- Motor neuron disorder
- Neuromuscular junction disorder
- Myopathy
- Spinal cord injury
- Stroke
- Complex regional pain syndrome

Differential Diagnosis

Etiology of Brachial Plexopathy

It is helpful to approach the differential diagnosis of brachial plexopathy by the common causes in the different anatomic regions where the brachial plexus is affected. The anatomic areas of interest are the supraclavicular, retroclavicular, and

infraclavicular. There are also causes of brachial plexopathy that tend to produce more diffuse plexus injury.

Supraclavicular

Birth Trauma

Lateral deviation of the head and neck to free the infant's shoulder, during both vaginal delivery and cesarean section, can lead to stretch injury of the upper brachial plexus. Such injuries can also occur from in utero causes, including compression of the fetal shoulder by the maternal symphysis pubis or sacral promontory, as well as by uterine anomalies that result in abnormally elevated intrauterine pressures [13]. The incidence of brachial plexopathy from birth trauma is 0.4 to 4 per 1000 live births [14]. It is called Erb palsy when the C5-C6 nerve roots are affected, resulting primarily in proximal arm weakness. When the C8-T1 roots are affected, the results are hand weakness, called Klumpke paralysis.

Trauma

Most commonly, trauma involves the upper plexus and is especially seen with closed traction, as in "burner" or "stinger" sports injuries (sudden separation of the shoulder and head due to contact) and pressure from backpack straps ("rucksack palsy"). The roots can be stretched but remain continuous, tear, or avulse from the spinal cord as possibilities. More direct trauma, such as from a stab wound or gunshot wound, can affect any portion of the plexus, but the supraclavicular portion is the most susceptible.

Intraoperative Arm Malpositioning

Postoperative brachial plexopathy may result from malpositioning of the arm during surgery [15].

Pancoast Syndrome

An apical lung tumor (usually small cell carcinoma) can extend into the supraclavicular brachial plexus, often being manifested with shoulder pain [16].

Neurogenic Thoracic Outlet

This syndrome is a rare condition in which a fibrous band extends from the lower cervical spine (cervical rib or transverse process) to the first rib. The T1 fibers are deflected and injured further by this fibrous band more than the C8 fibers are.

Infraclavicular

Postirradiation

Radiation therapy directed at the axillary lymph nodes can result in brachial plexopathy, which can occur months to years after radiation therapy. EMG studies may reveal evidence of conduction block and classic myokymia.

Metastatic Lymphadenopathy

A secondary neoplastic injury is usually due to compression from enlargement of involved axillary lymph nodes.

Regional Blocks

Infraclavicular brachial plexus injury has been identified as a complication of axillary regional blocks [17].

Heterotopic Ossification

The growing mass of heterotopic ossification about the shoulder can envelop and compromise the brachial plexus [18]. In midclavicular fractures, brachial plexopathy can be secondary to the initial trauma and also result from the development of heterotopic ossification [18].

Retroclavicular

Midclavicular Fractures

In midclavicular fractures, brachial plexopathy can be secondary to the initial trauma but also can result late from exuberant callus compression of the brachial plexus [18]. Retroclavicular brachial plexopathy, however, is rare and most often occurs in the context of wider spread plexopathy.

Diffuse Localization

Neuralgic Amyotrophy

Also called Parsonage-Turner syndrome, brachial amyotrophy, idiopathic shoulder girdle neuropathy [19], and brachial plexitis, neuralgic amyotrophy is a well-described syndrome of idiopathic monophasic brachial plexopathy that was well characterized by a large case series [20]. The initial symptom is onset during a few hours of severe continuous proximal upper extremity pain, which occurred in 90% of patients in this case series. After the onset of pain, weakness of the extremity usually develops within 2 weeks. Whereas sensory symptoms in the affected extremity are usually less pronounced than pain and weakness, they occur in 70% of patients. Pain decreases first, with an average pain duration of 28 days. Motor recovery begins within 6 months in most patients and with significant functional improvement; but in this case series, more than 70% of patients still had at least mild weakness detected on thorough strength examination at 3 years after weakness onset. Neuralgic amyotrophy can involve any part of the brachial plexus but tends to affect the upper plexus; 49% of patients have shoulder-proximal arm involvement.

Hereditary Neuralgic Amyotrophy

This is a similar condition but with a known genetic etiology, which is often autosomal dominant but is genetically heterogeneous.

Diabetic Cervical Radiculoplexus Neuropathy

Distinct from neuralgic amyotrophy is the recently described diabetic cervical radiculoplexus neuropathy [21]. This condition is associated with type 2 diabetes mellitus. Patients initially develop pain in the upper limb, often acutely, followed later by weakness and sensory changes, such as paresthesias, dysesthesias, or numbness. Associated autonomic symptoms (orthostasis, sudomotor changes) are common, as is weight loss. Electrodiagnosis reveals predominantly axonal neuropathy, whereas biopsy findings of involved nerves show axonal degeneration, ischemic injury, and perivascular inflammation. The condition is typically monophasic with improvement, but 21% of patients demonstrated recurrence [21].

Primary Neoplastic Peripheral Nerve Tumors

Local primary peripheral nerve tumors can cause brachial plexopathies that occur anywhere in the brachial plexus

but are rare and usually benign. Benign tumors are typically nerve sheath tumors, either schwannomas or neurofibromas (associated with neurofibromatosis type 1), and cause painless sensory loss and weakness [2]. In contrast, malignant peripheral nerve tumors in the brachial plexus tend to be painful [22,23].

Treatment

Initial

The treatment of brachial plexopathy needs to be customized to the individual patient and the cause of the brachial plexopathy. Pain can be the most disabling symptom but is usually effectively treated with neuropathic pain medications, such as gabapentin and tricyclic antidepressants, and analgesics, such as tramadol and opiates in cases of severe pain. Dosing is usually at the higher end of accepted ranges (such as gabapentin at 600mg three times daily or more) secondary to the pain severity of acute plexopathy, although duration of therapy may be brief. Levetiracetam has been used successfully to reduce refractory brachial plexopathy pain and to decrease opioid need [24].

Rehabilitation

When the muscles of the shoulder girdle are involved, therapy focused on positioning and shoulder range of motion can prevent secondary complications, such as adhesive capsulitis [25]. Directed exercise can be beneficial, with the caveat that exercise of muscles with neurogenic weakness from brachial plexus lesions to full exhaustion may be counterproductive on the basis of findings in exercise in patients with peripheral neuropathy [26]. Occupational therapy is often indicated when weakness from brachial plexopathy results in loss of function. Adaptive aids can be helpful when they are indicated, such as a shoulder sling to help reduce imbalance from proximal arm weakness from brachial plexopathy. Vocational rehabilitation may be indicated when the resultant disability from weakness affects the patient's ability to perform in the job setting.

Procedures

Brachial plexus blocks are rarely used but are possible for the treatment of severe pain from metastatic brachial plexopathy or severe acute brachial plexopathy. Increasingly, botulinum toxin injections, combined with surgery, serial casting, and physical and occupational therapy, are used to treat and to prevent shoulder and forearm pronation contractures as well as to optimize elbow range of motion in infants with obstetric brachial plexus injury [27]. However, botulinum use in this scenario has yet to be tested by randomized controlled trials.

Surgery

Surgery is an option in cases of traumatic plexopathy but has variable results. Surgical techniques such as nerve grafting, free muscle transfer, neurolysis, and neurotization are used. Surgeons who use these techniques frequently differ considerably in their approach to them, making conclusions

about their efficacy difficult. Surgery is an option in brachial plexus birth injuries, usually when persistent severe motor deficits are present after 3 to 8 months of age. A case series found improvement in surgically treated patients on a shoulder motion scale [28]. The location of injury affects selection of patients for surgery and surgical outcome. For example, postganglionic nerve root avulsion injuries may do better with earlier surgery [29]. Preganglionic avulsions are difficult to repair, but direct implantation into the spinal cord may help some patients [30].

Potential Disease Complications

Weakness from brachial plexopathy can result in joint instability or in joint and musculotendinous contractures of upper extremity joints. Complex regional pain syndrome may follow brachial plexopathy [31]. Secondary depression can be due to pain and loss of function. Insensate limbs are at risk for trauma neglect, infection, and amputation.

Potential Treatment Complications

Stretching and range of motion exercises for avoidance or treatment of contractures can acutely exacerbate neuropathic pain. Care to avoid shoulder impingement during range of motion exercises is important because of weak rotator cuff muscles. Insensate limbs become more susceptible to heat injuries, such as by hot packs or therapeutic ultrasound. Medicines used for brachial plexopathy pain can have side effects, which are specific to the particular medicine used. Surgery for brachial plexopathy may result in nerve or vascular injury.

353.8 Other nerve root and plexus disorders
353.9 Unspecified nerve root and plexus disorder
907.3 Late effects of injury to nerve root, spinal plexus, and other nerve of trunk
953.5 Injury to lumbosacral plexus
953.8 Injury to multiple sites of nerve roots and spinal plexus
953.9 Injury to nerve root and spinal plexus, unspecified site

ICD-10 Codes

G54.1 Lumbosacral plexus disorders
G54.8 Other nerve root and plexus disorders
G54.9 Nerve root and plexus disorder, unspecified
S34.21 Injury of nerve root of lumbar spine
S34.22 Injury of nerve root of sacral spine
S34.4 Injury of lumbosacral plexus
M54.15 Radiculopathy, thoracolumbar region
M54.16 Radiculopathy, lumbar region
M54.17 Radiculopathy, lumbosacral region

M54.18 Radiculopathy, sacral and sacrococcygeal region

Add seventh character for episode of care (S—late effects)

Definition

Lumbosacral plexopathy is an injury to or involvement of one or more nerves that combine to form or branch from the lumbosacral plexus. This involvement is distal to the root level.

The lumbar plexus originates from the first, second, third, and fourth lumbar nerves (Fig. 144.1). The fourth lumbar nerve makes a contribution to both the lumbar and the sacral plexus. There is typically a small communication from the twelfth thoracic nerve as well. As in the brachial plexus, these nerve roots divide into the dorsal rami and the ventral rami as they exit through the intervertebral foramina. The dorsal or posterior rami innervate the paraspinal muscles and supply nearby cutaneous sensation. The ventral or anterior rami of the lumbar plexus form the motor and sensory nerves to the anterior and medial sides of the thigh and the sensation on the medial aspect of the leg and foot. The undivided anterior primary rami of the lumbar and sacral nerves also carry postganglionic sympathetic fibers that are mainly responsible for vasoregulation of the lower extremities. The branches of the lumbar plexus include the iliohypogastric, ilioinguinal, genitofemoral, femoral, lateral femoral cutaneous, and obturator nerves [1]. The lumbar portion of the plexus lies just anterior to the psoas muscle [2].

The sacral plexus innervates the muscles of the buttocks, posterior thigh, and leg below the knee and the skin of the posterior thigh and leg, lateral leg, foot, and perineum. It is formed from the lumbosacral trunk to include L5 and a portion of L4 as well as the S1 to S3 (or S4) nerve roots (Fig. 144.2). The anterior primary rami of S2 and S3 nerve roots carry parasympathetic fibers that mainly control the urinary bladder and anal sphincters. The triangular sacral plexus lies on the anterior surface of the sacrum, in the immediate vicinity of the sacroiliac joint and lateral to the cervix or prostate [1]. The branches of the sacral plexus include the superior and inferior gluteal nerves, the posterior cutaneous nerves of the thigh, the

FIGURE 144.1 The lumbar plexus and its peripheral terminal branches. The shaded portions represent the posterior divisions of the ventral primary rami; those not shaded are either the ventral primary rami or their anterior branches. In this diagram, the nerve to the psoas major arises from the femoral nerve, as opposed to directly from the spinal nerve region. (From de Groot J, Chusid JG. *Correlative Neuroanatomy*, 21st ed. Norwalk, Conn, Appleton & Lange, 1991.)

lumbosacral trunk that becomes the sciatic nerve with both tibial and peroneal divisions, and the pudendal nerve.

Etiology

Lumbosacral plexopathy has been recognized as a clinical entity or complication in a variety of surgical procedures, trauma, and obstetric surgery or delivery and as a clinical finding or sequela in treatment of pelvic tumors.

Trauma

Traumatic pelvic fractures have a 30.8% incidence of lumbosacral plexus injury [3,4]. The incidence and severity of traumatic lumbosacral plexopathy increase with the number of pelvic fracture sites and fracture instability [4]. Sacral fractures have typically been considered of secondary importance in conjunction with pelvic trauma [5]. However, sacral fractures have become recognized as an essential consideration in pelvic trauma because of their high association with lumbosacral nerve deficits. This can have a profound influence on prognosis and level of functional recovery [3,6]. The more common sacral fractures are typically the compression or avulsion fractures of the sacral ala, which can occur in lateral compression and anterior-posterior compression pelvic fractures [7]. Fractures of the sacral neuroforamina or midline sacral fractures may also occur. Fractures of the sacrum can increase the incidence of

neurologic injury in pelvic trauma to between 34% and 50% because of its proximity to the sacral nerve roots [7].

Gunshot wounds and motor vehicle accidents have long been recognized as potential causes of lumbosacral plexus injuries. In a retrospective comparison of patterns of lumbosacral plexus injury in motor vehicle crashes and gunshot wounds, individuals with gunshot wounds had a greater chance of involvement of the upper portion of the plexus in comparison to individuals who sustained a motor vehicle crash. Lower plexus injuries were more common in victims of motor vehicle accidents as opposed to gunshot wounds [8].

Finally, trauma is a common cause of retroperitoneal hemorrhage, which can injure the lumbosacral plexus.

Labor and Delivery

The lumbosacral plexus may be compressed as a complication of labor and delivery. The incidence of neurologic injury that is reported in the literature for postpartum sensory and motor dysfunction is relatively low at 0.008% to 0.5% [9,10]. Factors associated with nerve injury were nulliparity and a prolonged second stage of labor; assisted vacuum or forceps vaginal delivery also had some positive association. Women with nerve injury spent more time pushing in the semi-Fowler lithotomy position. During the second stage of labor, direct pressure of the fetal head may compress the lumbosacral plexus against the pelvic rim, which may result in nerve injury [11,12].

FIGURE 144.2 Schematic representation of the sacral plexus. The shaded portions signify the posterior divisions of the ventral primary rami; the unshaded aspects are the anterior branches of the ventral primary rami. (From de Groot J, Chausid JG. *Correlative Neuroanatomy*, 21st ed. Norwalk, Conn, Appleton & Lange, 1991.)

Iatrogenic

Gynecologic surgery is thought to be one of the most common causes of femoral nerve injury (see Chapter 54) and lumbosacral plexus nerve injuries. Abdominal hysterectomy is the surgical procedure that has been most frequently implicated [13,14]. The mechanisms of neurologic injury that have been established include improper placement or positioning of self-retaining or fixed retractors, incorrect positioning of the patient in lithotomy position preoperatively or prolonged lithotomy positioning without repositioning, and radical surgical dissection resulting in autonomic nerve disruption [15].

Lumbosacral injury has also been noted after appendectomy and inguinal herniorrhaphy. Patients who are thin, diabetic, or elderly are at increased risk for such an injury. Injury to the lumbosacral plexus with clinical findings occurs in up to 10% of hip replacement procedures, and injury that is subclinical but detected electromyographically occurred in up to 70% of patients [16].

In individuals receiving anticoagulant therapy or with acquired or congenital coagulopathies, retroperitoneal hemorrhage causing lumbosacral plexopathy may occur with no precipitating injury [17,18].

Retroperitoneal hematoma has also been documented as a rare but potentially serious complication after cardiac catheterization [19,20]. In a review of 9585 femoral artery catheterizations, a reported retroperitoneal hematoma rate of 0.5% occurred. In patients undergoing stent placement, there was evidence of lumbar plexopathy involving the femoral, obturator, and lateral femoral cutaneous nerves, and the condition was typically completely reversible [21,22]. Femoral vein catheterization for dialysis has also been documented as a cause of hemorrhagic complications and retroperitoneal hemorrhage [23].

Case reports have also identified patients sustaining lumbosacral plexopathy after undergoing aortoiliac bypass grafting for abdominal aortic aneurysm. The proposed mechanism for this rare complication, with fewer than 80 patients reported in the literature, is neural ischemia secondary to interruption of the blood supply to the lumbosacral plexus or caudal portion of the spinal cord [24,25].

Oncologic

Both pelvic malignant neoplasms and treatment of pelvic tumors can damage the lumbosacral plexus. Lumbosacral radiculopathy is most common with gynecologic tumors,

sarcomas, and lymphomas. Neoplastic plexopathy is characterized by severe and unrelenting pain, typically followed by weakness and sensory disturbances [26]. Pelvic radiation therapy may cause a delayed lumbosacral plexopathy that can occur 3 months to 22 years after completion of treatment; the median amount of time from the completion of treatment to onset of symptoms is about 5 years [27–29]. Chemotherapeutic agents can also cause symptoms of lumbosacral radiculopathy. Cisplatin, 5-fluorouracil, mitomycin C, and bleomycin have been implicated in the majority of these plexopathies [2]. Metastatic or tumor extension into the lumbosacral plexus and malignant psoas syndrome have been described in the literature. Malignant psoas syndrome was first reported in 1990. It is characterized by proximal lumbosacral plexopathy, painful fixed flexion of the ipsilateral hip, and radiologic or pathologic evidence of ipsilateral psoas major muscle malignant involvement [2].

Diabetic Amyotrophy

Diabetic and nondiabetic lumbosacral radiculoplexus neuropathies have been documented in the literature. Diabetic lumbosacral radiculoplexus neuropathy is a subacute, painful asymmetric lower limb neuropathy that is associated with significant weight loss (at least 10 pounds), type 2 diabetes mellitus, and relatively recent diagnosis of diabetes with relatively good glucose control [30]. The underlying pathophysiologic mechanism is thought to be immune mediated with microvasculitis of the nerve rather than a metabolic issue caused by diabetes; nondiabetic lumbosacral radiculoplexus neuropathy has also been documented with similar clinical and pathophysiologic features [30–34]. The similar clinical symptoms, findings, and response to treatment suggest that the metabolic changes from diabetes may not be the cause of these symptoms, although impaired glucose tolerance has been noted in nondiabetic lumbosacral radiculoplexus neuropathy [32].

Vascular

Vascular causes of lumbosacral plexopathies may include diabetic amyotrophy and connective tissue diseases that may be associated with vasculitis, such as systemic lupus erythematosus, rheumatoid arthritis, and polyarteritis nodosa [35]. Further, a recently published case report described acute lumbosacral plexus injury secondary to direct compression by an internal iliac artery aneurysm [36]. If a vascular cause is suspected, the aorta and iliac vessels must be evaluated for disease or occlusion [37–39].

Symptoms

Plexopathies may vary considerably in their presentation, depending on the location and degree of involvement. Lumbosacral plexopathy often begins with leg pain radiating to the low back and buttocks and progressing posterolaterally down the leg, soon followed by symptoms of numbness and weakness. Lumbosacral plexus injuries are often associated with a footdrop and sensory changes to the top of the foot. A plexopathy involving the upper lumbar roots may primarily be manifested by femoral and obturator nerve symptoms. Femoral nerve injury typically is manifested with iliopsoas or quadriceps weakness, and there may be sensory deficits over the anterior and medial thigh as well as the anterior medial

aspect of the leg [13]. Obturator injury has also been seen in upper plexus injuries with weakness of the hip adductors [10] and sensory changes in the upper medial thigh.

Diabetic plexopathy typically starts as an identifiable onset of asymmetric lower extremity symptoms that most typically involve the thigh and hip with pain that progresses to include weakness, which then becomes the main disabling symptom. In a few months, this usually evolves into bilateral symmetric weakness and pain with distal as well as proximal involvement. Although motor findings are prominent, sensory and autonomic nerves have also been shown to be involved [29].

Bowel and bladder injuries tend to occur in cases in which there is bilateral sacral root involvement. Sexual dysfunction has been documented in both bilateral and unilateral sacral injuries and pelvic trauma. Lumbosacral plexus injuries are much more common in pelvic and sacral fractures but have been documented in acetabular fractures and midshaft femoral fractures as well [3,6,26].

Physical Examination

Clinical examination to evaluate for a lumbosacral plexopathy involves neurologic assessment to include motor strength testing, sensory testing, muscle stretch reflexes, tone, and bowel and bladder function. The pattern of sensory loss, asymmetric reflexes, or weakness is suggestive of multiple nerve or root level involvement. It is important to differentiate a suspected plexus injury from single root level involvement, suggesting a radiculopathy, or more generalized nerve changes consistent with peripheral neuropathy. A detailed examination of the bilateral lower limbs, including skin sensory testing of all dermatomes, manual muscle testing of all myotomes, and examination of the patellar and Achilles deep tendon reflexes, can reveal neurologic deficits that can aid in this differentiation. In addition, it may be necessary to evaluate lower sacral involvement by physical examination of a patient's external anal sphincter tone, particularly if complaints include bowel and bladder incontinence. Edema or swelling in one lower extremity may be suggestive of a pelvic mass or lumbosacral plexus involvement rather than a more global peripheral neuropathy [38] or possible retroperitoneal hematoma or pelvic malignant neoplasm [2].

Functional Limitations

Functional limitations depend on which portions of the lumbar or lumbosacral plexus have been injured and the severity of the injury. Patients frequently present with some type of difficulty with mobility and ambulation. Activities such as transferring from one surface to another, rising from a chair, ambulation, grooming, bathing, dressing, and cooking may potentially be affected. These functional limitations may have far-reaching consequences on one's ability to live independently and to continue in one's chosen vocation.

Diagnostic Studies

Electrodiagnostic Testing

The electrodiagnostic evaluation of lumbosacral plexopathy is one of the most effective tools available for differentiation

of a specific pattern and severity of nerve involvement. Guided by a focused history and physical examination, the skilled electromyographer can use testing of both proximal and distal sensory and motor nerves as well as muscle needle examination to determine whether there is radicular involvement, lumbar or lumbosacral plexus involvement with multiple nerves involved but no paraspinal involvement, or a more generalized picture consistent with a peripheral neuropathy.

Testing for upper lumbar plexopathy may include lateral femoral cutaneous nerve, saphenous nerve, posterior femoral cutaneous sensory nerve, and femoral motor nerve studies. Side-to-side comparison is recommended to assess for asymmetry in these technically challenging studies. Sensory involvement without motor involvement suggests a lesion distal to the dorsal root ganglion. Studies to evaluate the lumbosacral plexus and lumbosacral roots include sural and superficial peroneal sensory studies, H reflex, and peroneal and tibial motor conduction studies. Depending on the timing of the injury, nerve conduction studies can demonstrate a decrease in amplitude for the sensory nerve action potentials starting at 5 to 6 days and for compound muscle action potentials starting at 2 to 4 days [8].

The needle electromyographic examination is likely to be the most useful electrodiagnostic technique [8]. Careful examination of proximal and distal musculature demonstrates a pattern of muscle membrane instability in more than one peripheral nerve from different root levels without involvement of the paraspinal muscles. The pattern of muscle membrane instability indicates whether the injury appears to be a neurapraxia with conduction block, axonotmesis, or neurotmesis with Wallerian degeneration and poor prognosis for reinnervation. Increased insertional activity may be seen in the involved musculature after 7 to 8 days, with positive waves and fibrillations starting at 10 to 30 days but being most prominent at 21 to 30 days after injury [8]. Decreased recruitment is noted immediately after injury, and this may be the only change on needle electromyographic examination in the first few days if the nerve is partially intact.

Imaging Studies

Computed tomography and positron emission tomography can be useful in determining the presence of a structural mass in the pelvic region. Computed tomographic scans, along with abdominal ultrasonography, may be used to diagnose a retroperitoneal hemorrhage. Both computed tomographic scanning and magnetic resonance imaging have been used to evaluate the lumbosacral plexus. Magnetic resonance imaging has been found to be more sensitive than computed tomography for diagnosis of cancer-related lumbosacral plexopathy [40]. High-resolution magnetic resonance neurography with T1-weighted fast spin echo and fat-saturated T2-weighted fast spin echo has been used to study the lumbosacral plexus and the sciatic nerve [41]. Plain radiographs are useful as a screening tool for suspected aneurysms or malignant disease.

Differential Diagnosis

- Spinal cord injury
- Cauda equina injury
- Lumbosacral nerve root injury
- Multiple peripheral nerve injuries
- Anterior horn cell diseases
- Myopathies
- Occlusion of the aorta

Treatment

Initial

Initial treatment is based on both the presenting symptoms and the cause of the lumbosacral plexopathy. For example, many obstetric lumbosacral plexus symptoms are treated conservatively. Pelvic masses or a retroperitoneal hemorrhage may require surgical or medical intervention. Neoplastic or radiation-based plexopathy symptoms may need specific medical management, chemotherapy, or possibly surgery. If edema control is necessary, leg elevation and compressive stockings may be of some benefit. Medication for neuropathic pain might include gabapentin, duloxetine, or pregabalin. Tricyclic antidepressants may also be helpful. Opioids and nonsteroidal anti-inflammatory drugs may also provide pain relief. Use of nonsteroidal anti-inflammatory drugs is contraindicated, however, when hemorrhage is suspected. Various immunomodulation therapies for diabetic amyotrophy, including corticosteroids, cyclophosphamide, intravenous immune globulin, and plasmapheresis, have been described in a number of case series, most of which report positive outcomes with regard to resolution of pain and weakness [29,34]. To date, only one multicenter, double-blind controlled study of intravenous methylprednisolone in diabetic amyotrophy exists, but it is as yet unpublished [42]. Therefore, at this time, the literature still lacks strong evidence from randomized controlled trials to definitively recommend the use of immunotherapy for diabetic lumbosacral radiculoplexus neuropathies.

Rehabilitation

Rehabilitation aims to maximize mobility and functional independence. The goals of rehabilitation are preservation of joint range of motion and flexibility, joint protection, and pain management; these goals depend on a good physical examination to determine what neurologic and functional deficits are present.

One of the primary rehabilitation concerns in an individual with nerve involvement in the lumbar or lumbosacral plexus is safe mobility and ambulation. The patient should be evaluated for the need for an assistive device, such as a cane or a walker, with ambulation. Patients with significant footdrop impairing gait benefit from prescription of ankle-foot orthoses, with dorsiflexion assist as an option. Energy conservation techniques and care of insensate feet are key treatment tools. Symptoms of

lumbosacral plexopathy may be subtle and may be difficult to appreciate in a clinical setting. Physicians need to address potentially sensitive issues such as work limitations, sexual functioning, and sensory changes in the pelvic and inguinal areas.

Procedures

Sympathetic nerve blocks and chemodenervation have both been used to ameliorate pain. This can be both diagnostic and treatment oriented in helping to confirm the suspected diagnosis. Sacral nerve stimulation has been evaluated for adjunctive treatment of lumbosacral plexopathy, but further research is required for its effectiveness to be determined [17].

Surgery

Lumbosacral plexus injuries associated with pelvic or sacral fractures or with gynecologic surgery are often treated conservatively [13], although it has been documented that long-term sequelae can occur. Nerve reconstruction including nerve grafting has been reported in an attempt to restore some lower extremity function [43]. Microsurgical treatment of lumbosacral plexopathies for neurolysis and nerve grafting has been used in the retroperitoneal space. In a series of 15 cases, the muscles that benefited the most from surgery were the gluteal and femoral innervated muscles. The more distal musculature did not seem to show much benefit [44]. Whereas motor improvement is an important consideration, pain is often extremely debilitating in patients with a lumbosacral plexopathy and may block or limit rehabilitation. Pain relief is one of the major goals for surgical intervention. Surgical resection of a tumor may also be indicated in certain cases with lumbosacral plexopathy [26].

Potential Disease Complications

Potential complications of lumbosacral plexopathy include joint contractures, limited mobility, weakness, falls secondary to weakness or sensory loss, bowel or bladder incontinence, diminished or absent sensation, skin breakdown, sexual dysfunction, and significant decrease in functional independence from these complications. The rare complication of complex regional pain syndrome type II has also been reported [45].

Potential Treatment Complications

Treatment complications may include skin breakdown under orthoses and increased weakness if the rehabilitation program is too aggressive. Medication side effects are dizziness, somnolence, gastrointestinal irritation, and ataxia due to anticonvulsants; dry mouth, urinary retention, and atrioventricular conduction block due to tricyclic antidepressants; and dependence, dizziness, somnolence, and constipation due to opioid pain medications. Nonsteroidal anti-inflammatory drugs and analgesics can also have significant side effects that affect the gastrointestinal and renal systems as well as the liver.

G82.20 Paraplegia, unspecified
S02.91 Unspecified fracture of skull
S02.92 Unspecified fracture of facial bones
Add seventh character for S02 (A—initial encounter for closed fracture, B—initial encounter for open fracture, D—subsequent encounter for fracture with routine healing, G—subsequent encounter for fracture with delayed healing, K—subsequent encounter for fracture with nonunion, P—subsequent encounter for fracture with malunion, S—sequela)
S06.0 Concussion
S06.9X Unspecified intracranial injury; add seventh digit for duration of loss of consciousness
Add seventh character to S06 for episode of care
B99.9 Unspecified infectious disease

Definition

In 2005, the U.S. Department of Veterans Affairs officially adopted the term *polytrauma*, originally defined as an injury to the brain in addition to other body parts. The definition

changed in 2009 to be more encompassing: “two or more injuries sustained in the same incident that affect multiple body parts or organ systems and result in physical, cognitive, psychological, or psychosocial impairments and functional disabilities [1,2].”

The sequelae of polytrauma may include physical, cognitive, and psychological impairments. If a brain injury is involved, the severity typically guides the course of rehabilitation [3]. Other common disabling conditions include limb extremity trauma or amputation, spinal cord injury, neurosensory impairments, mental health disorders, and extreme soft tissue injury.

Because of the nature of modern military combat and violence in society, there is an increased risk for polytrauma injuries. Current combat-related polytrauma injuries are frequently caused by exposure to high-energy blasts or explosions [4]. Other causes of polytrauma may include severe motor vehicle accidents, falls, suicide attempts, accidental drug overdoses, and assaults. Advanced trauma life support permits increased survival among those with even the most devastating injuries (Table 145.1).

Polytrauma war-related injuries as well as civilian-based injuries occur more frequently in the younger population and predominantly in males. In noncombat conditions, active-duty men are 2.5 times more likely to have a traumatic brain injury. Military reports indicate that more than 27,000 service members serving in the current conflicts were injured between December 2001 and April 2012; of those, 49% sustained injuries classified as polytrauma. Of those injured as a result of combat operations, 62% had polytrauma injuries (K. Gross, personal communication, February 1, 2013). In the military polytrauma population, 1581 amputees have been treated in the military treatment facilities [5]. Civilian polytrauma frequency statistics are not available at this time [6,7].

Symptoms

Whereas many symptoms of polytrauma are immediately recognized, others are more subtle. Symptoms related to traumatic brain injury include cognitive, emotional, and physical impairments (see Chapter 162).

Cognitive deficits in patients with moderate to severe brain injury may include difficulties with speech and language, executive function, memory, concentration, and judgment. Irritability, anxiety, depression, and emotional lability are commonly observed. Physical symptoms of polytrauma commonly include motor and sensory deficits as well as more subtle complaints, such as headache, dizziness, fatigue, and dyssomnias. Pain is common and arises from multiple causes, complicating pain management.

Physical Examination

A thorough physical examination is essential in the evaluation of a patient who has sustained polytrauma. A mechanism of injury-directed review of systems is suggested [5]. If the mechanism of injury is blast related, the examination emphasizes testing for barotrauma to air- or fluid-filled organs. A thorough neurologic examination with complete assessment of cranial nerves (including olfactory), motor strength, sensation, reflexes, and coordination and a neuropsychological evaluation are recommended when central nervous system involvement is suspected.

A multidisciplinary approach commonly requiring specialty consultants to participate in the assessment is necessary for comprehensive care of these complex patients. Special attention is paid to the assessment of skin and soft tissue. The ideal approach is a patient-centered interdisciplinary evaluation and treatment plan coordinated by physiatry.

Functional Limitations

Polytrauma patients have multiple functional limitations based on the severity and number of physical and cognitive impairments. Hearing and visual field deficits affect everyday life functions and can make educational and vocational goals difficult to achieve. Lower extremity muscle weakness often impairs ambulation and creates a safety risk from falls. Upper extremity weakness and spasticity impair the patient's ability to do everyday activities such as dressing, hygiene, and handwriting. Cognitive deficits affect the ability to work and to perform roles related to parenting and living independently. Particularly in the early phase of recovery, some patients may require continuous surveillance to prevent wandering or self-injurious behavior. Later in recovery, driving can be achieved in some patients after passing of a driving evaluation, which may identify necessary modifications to the current vehicle. Many polytrauma patients will experience psychosocial problems. Traumatic brain injury, stress, and mental health-related issues predispose patients to depression, anger, and mood swings. Those with brain injuries may experience significant personality changes affecting interpersonal relationships, vocational rehabilitation, and quality of life.

Diagnostic Studies

Imaging Studies

Because of the complex nature of injuries, several different imaging modalities are used to assess the central nervous

Table 145.1 Blast Injury

	Etiology of Injury	Organ Systems Affected	Examples
Primary	Barotrauma	Organs with gas-fluid interface	Ear, lung, and bowel perforations
Secondary	Fragment, shrapnel	Soft tissue, penetrating head injuries	Penetrating traumatic brain injury
Tertiary	Displacement of body from combined pressure loads	Soft tissue, orthopedic, head injury	Broken femur from forceful displacement
Quaternary	Miscellaneous (e.g., crush, burns, object displacement)	Any organ system can be affected	Falling building causing crush injury

system in the polytrauma patient. In general, central nervous system injury is assessed by a combination of computed tomography and magnetic resonance imaging. Magnetic resonance imaging may be challenging in both military and civilian populations because of the higher incidence of retained fragments or past medical history involving a metal implant. Post-traumatic encephalomalacia, hydrocephalus, intracranial hemorrhage, diffuse axonal injury, cerebral contusions, mass effect, degree of atrophy, and spinal cord injury can be assessed by magnetic resonance or computed tomographic imaging.

Routine radiographs are often sufficient to assess axial, musculoskeletal, and visceral injuries. Other imaging techniques, such as computed tomography, bone scan, magnetic resonance, and ultrasonography, can be used when more detailed examination is necessary or for assessment of secondary complications.

Electrodiagnostics

Patients with polytrauma often sustain damage to the peripheral nervous system. A review of 33 active-duty patients admitted to the Tampa Polytrauma Rehabilitation Center revealed multiple cases of plexopathy and peripheral nerve damage due to exposure to blasts, penetrating wounds, crush injuries, and motor vehicle collisions. In this study, upper extremity nerve damage was more common than lower extremity nerve damage; multiple nerve injuries were more common than mononeuropathy [7]. Electromyography and nerve conduction studies should be considered as part of the assessment of a polytrauma patient.

Electroencephalography is a useful tool in diagnosis of post-traumatic epilepsy or encephalopathy. Seizure control and treatment of post-traumatic epilepsy are important for maximizing goal attainment during the rehabilitation process. Long-term electroencephalographic monitoring can aid in diagnosis of post-traumatic epilepsy as well as in the identification of subclinical seizures or seizure activity in patients with severe brain injuries who have not regained consciousness.

Polysomnography and actigraphy can be helpful in assessing for dyssomnias that may result after a polytrauma injury. Both sleep efficiency and sleep duration are important components of recovery, which is especially true in patients with concomitant brain injury [8].

Vascular Studies

Thromboembolic disease is a consequence of polytrauma and subsequent immobility after injury. Venous Doppler ultrasonography is frequently used to detect deep venous thrombosis in the extremities. In addition, computed tomography angiography is the diagnostic study of choice to evaluate for pulmonary embolism. Arterial Doppler ultrasonography may also be useful in the assessment of traumatic amputations to determine adequate perfusion of the residual limb.

Arterial dissection has also been documented to occur secondary to polytrauma. Traditional angiography and magnetic resonance angiography are both useful to explore the extent of dissection and superimposed thrombus after traumatic dissection.

Functional Testing

Functional testing uses sets of tests to determine performance or limitations. This testing is routinely performed by speech-language pathologists, physical therapists, and occupational therapists. Whereas overt injuries may be manifested with obvious functional deficits, milder or subclinical injuries in the presence of massive traumatic injuries may be unrecognized initially but need to be identified throughout the rehabilitation process. The intradisciplinary assessment of a polytrauma patient should include all members of the rehabilitation team to develop the full functional picture of each individual patient.

Disturbances in balance, hearing, and vision are commonly reported by polytrauma patients. Examples may include tinnitus, dizziness, and blurry vision. These disturbances result in sensory processing difficulties that affect cognitive functioning, mobility, independent performance of activities of daily living, and successful integration into the community. Evaluation and rehabilitation of the multisensory disturbances should be therapeutically integrated among specialty providers. Physical therapists with specialized training in balance disorders may perform computerized dynamic posturography to help determine the etiology of the impairment. Speech-language pathologists may be employed to evaluate dysphagia by bedside examination or video swallow study.

Neuropsychological and Psychological Evaluations

A comprehensive battery of neuropsychological and psychological tests is necessary to determine the full spectrum of cognitive and psychological sequelae from polytrauma injuries. This is typically completed once the person is medically stable, is in an acute rehabilitation program, and has emerged from a postinjury confusional state such as post-traumatic amnesia or delirium. Evaluations may be repeated to address different clinical questions during the course of recovery. Initially, assessment helps identify cognitive and emotional impairments that should be a focus of treatment. Repeated evaluations may be useful in making decisions about additional treatment needs, residential placement independence capacity, and future vocational or educational endeavors.

Differential Diagnosis

Differential diagnosis for patients sustaining polytrauma injuries is complex for seemingly simple problems. Even the cause of the injury is frequently debated. For example, brain injury can be caused by primary, secondary, and tertiary blast injuries or a combination of the three and may be traumatic or anoxic. A broad differential should be included when any problem with a polytrauma patient is considered.

The clinician must maintain a high index of suspicion for possible central nervous system infection when patients with a history of penetrating head injury present with such vague complaints as confusion, fatigue, and functional decline. Likewise, patients with a history of penetrating abdominal wounds may present with vague abdominal

complaints, and an aggressive evaluation may be required for retained shrapnel and possible abscess. Musculoskeletal complaints may also be challenging, and evaluation for retained shrapnel causing impingement or nerve injury should be explored. Any complaint that does not respond to treatment as expected should be explored and the differential diagnosis widened in an effort to treat this challenging population of patients. In this regard, the potential for development of chronic pain or somatoform disorders, post-traumatic stress disorder, depression, or other psychological conditions should be considered.

Differential Diagnosis

Conversion disorder
Somatoform disorder
Malingering

Some potential diagnoses are actually the traumas or injuries of polytrauma:

Dementia or cognitive disorder NOS
Normal-pressure hydrocephalus
Toxic exposure
Fibromyalgia
Mycobacterial infection
Mycoplasmal infection
Infectious disease
Drug and alcohol abuse
Medication side effects

Others are potential differential diagnoses:

Progressive dementias
Sleep apnea
Multiple sclerosis
Neoplasms
Autoimmune disease (e.g., rheumatoid, lupus, vasculitis)
Other infectious diseases (Lyme disease, syphilis, poliomyelitis, human immunodeficiency virus infection, Epstein-Barr virus infection)

Treatment

Initial

Dramatic improvement in survival is attributed to advanced trauma life support. The initial treatment is predominantly focused on maintaining medical stability and preventing further injury. With enhanced survival of catastrophic injuries, disability and impairments are increased, thus dictating the complexity of multidisciplinary rehabilitation.

Rehabilitation

Polytrauma rehabilitation is challenging in that multiple impairments must be rehabilitated concurrently. The rehabilitation process begins in the acute medical setting, such as a military treatment facility or level I trauma hospital, with the initiation of individual physical, occupational, and speech therapy. Treatment in the acute medical setting will lay the foundation for the rest of the rehabilitation process.

Successful rehabilitation of polytrauma patients requires both multidisciplinary medical care and interdisciplinary rehabilitation care. The interdisciplinary patient-centered rehabilitation team led by a physiatrist should consist of speech therapists, physical therapists,

occupational therapists, nurses, blind rehabilitation specialists or certified low vision therapists, audiologists, recreational therapists, psychologists, social workers, rehabilitation counselors, family therapists, prosthetists, and others working together to minimize disability, to maximize independence, to offer psychosocial support, and to provide a rehabilitation regimen specific to each patient's individual needs [9]. The polytrauma patients should be observed with a rehabilitation model of care from initial consultation to long-term rehabilitation care or community reintegration.

Mobility issues should be discussed with the patient or caregiver, and the most appropriate source of mobility should be considered for each individual patient. With choice of mobility, a provider must identify which type of mobility assistance provides the highest degree of independent function with the lowest degree of long-term loss of function. Some polytrauma patients are able to use manual wheelchairs, offering them a higher level of independence, whereas other polytrauma patients and their caregivers benefit from power mobility. Pressure mapping of chair cushions should also be considered in developing chairs for this population. Prosthetists and orthotists are integral members of the rehabilitation team when mobility needs of the amputee are addressed.

During the past years of conflicts in the Middle East, there has been an increase in the number and severity of urinary tract, rectal, and external genital injuries in polytrauma patients. Surgeons are faced with testicular salvage, reconstruction, and colostomies. There is an increased need for incorporating urologic care into the care of these complex injuries. The rehabilitation team faces challenges of voiding dysfunction, erectile dysfunction, infertility, and long-term psychological effects [5].

Patients with polytrauma also have increased metabolic demands. These metabolic demands are driven by factors such as healing tissue, diffuse spasticity, and rigors of the rehabilitation process. Nutrition can be further complicated by the risk of aspiration, which may require dietary changes, use of percutaneous endoscopic gastrostomy or jejunostomy, and parenteral nutrition. Including a registered dietitian on the team can be extremely beneficial to these patients.

Telemedicine is an emerging technology that has proved to be an effective tool to address rehabilitation needs in this population. In the VA Polytrauma System of Care, a telehealth network was developed in 2006 to connect the interdisciplinary rehabilitation teams. This has enabled provider continuity and coordination of care from initial contact to community reintegration. Telehealth also provides enhanced options for patient access to care [10].

Multifaceted aspects of physical, psychosocial, financial, and reintegration challenges are vast. Resources for polytrauma patients are extremely individualized on the basis of the nature of the injuries. For example, patients may require special adapted housing, durable medical equipment, cognitive and physical prosthetics, vehicle modification, and mobility devices. The physiatrist has a critical role as a patient advocate. A strong working relationship with social services and caregivers is integral to the effective definition of needs and available resources. This can be a challenging but rewarding process.

Procedures

During the rehabilitation process, various interventions may be used to augment the efforts of the multidisciplinary team. Chemodenervation, intrathecal baclofen pumps, and serial casting can help reduce spasticity and improve overall mobility, hygiene, pain, caregiver burden, and function. Negative pressure wound therapy with vacuum-assisted closure may be used for large or slowly healing traumatic or postsurgical wounds, and débridement may be necessary [11]. Interventional pain procedures, trigger point and peripheral joint injections, and peripheral nerve blocks are often used to treat nociceptive pain when more conservative treatments fail. Spinal cord and peripheral nerve stimulator trials and subsequent placement are becoming more common for treatment of refractory pain [12].

Surgery

Because of the complexity of management necessary for the polytrauma patient, multiple surgical interventions may be required during the initial acute medical setting and acute rehabilitation period. Surgical examples include but are not limited to tracheostomies, percutaneous gastrostomy tubes, and external fixators. Patients may also require readmission to the hospital for subsequent surgeries, and an additional stay in the rehabilitation unit may allow the attainment of further independence goals. Patients with hydrocephalus may require placement of a ventriculoperitoneal shunt. Finally, reconstructive procedures for facial deformities, revision of skin grafts and scars, and resection of heterotopic ossification may be required in the late post-acute rehabilitation stage.

Patients who have sustained crush injuries may require fasciotomies as a result of compartment syndrome. Many patients who have sustained severe head trauma will require partial craniectomy both for removal of blood accumulation and for avoidance of further damage from cerebral edema. The removed portion of the skull is frequently unsalvageable because of fragmentation injuries. If the skull plate is salvageable, it may be either frozen or implanted into the abdominal wall for use at a later date.

The polytrauma patient frequently requires repeated surgical interventions during the acute hospitalization phase. Multiple revisions of amputated limbs as well as staged interventions for burned patients, such as repeated skin grafting, may be required.

Potential Disease Complications

Explosions have the potential to inflict multiple and severe trauma that few U.S. health care providers outside the military and the Veterans Administration have experience treating. The acute complications vary by the mechanism and pattern of trauma. Such complications can include air embolism, compartment syndrome, rhabdomyolysis, renal failure, seizures, hemorrhage, increased intracranial pressure, infections, meningitis, and encephalopathy. Early complications that follow major burns include bacterial infections, septicemia, deep venous thrombosis, pulmonary embolism, renal failure, hypovolemic shock, jaundice, glottic edema, and ileus.

Table 145.2 Common Infections in Polytrauma

Traumatic Brain Injury [13,14]	Spinal Cord Injury [15]	Amputation	General and Orthopedic [16]
Pneumonia Surgical site Urinary tract infection	Urinary tract infection Pneumonia Infected pressure wound	Skin Surgical site	Urinary tract infection Pneumonia Skin or soft tissue infection

During the acute rehabilitation stage of care, there is overlap of potential complications. However, some variable patterns emerge, depending on whether the major injury is traumatic brain injury, spinal cord injury, burn, or limb amputation.

The risk of heterotopic ossification exists for traumatic brain injuries, spinal cord injuries, burns, and amputations independently; thus, concern for increased risk exists when concomitant injuries are present. Heterotopic ossification is of great concern in this population as it can decrease function, lead to increased pain, and limit rehabilitation potential (see Chapter 130).

Mental health complications are common in the polytrauma patient. Diagnoses include depression, post-traumatic stress and anxiety disorders, adjustment disorders, body image issues, and behavioral or emotional dysregulation. Any or all of these can have an impact on medication or treatment compliance and general recovery.

It is important to include an infectious disease specialist in the care of the polytrauma patient, particularly for those patients who have a recent history of exposure to endemic infections. An example of this may be an infection related to *Acinetobacter baumannii* in a combat-related polytrauma patient returning from Afghanistan [13] (Table 145.2).

Cognitively impaired polytrauma patients are prone to falls because of compounding spasticity, visual impairment, impulsivity, or vestibulocochlear deficits. Along with fall issues, understanding the etiology and ramifications of the patient's other injuries is important to map out a safe rehabilitation process. Patients' families need to be educated on issues such as skin integrity, appropriate transfers, fall avoidance, proper wheelchair transfer and use, physical limitations, weight-bearing precautions, balance issues, and emotional stability in specific patients [17].

Potential Treatment Complications

Polypharmacy, side effects of medications, addiction to prescription pain medications, and surgical and procedural complications exist in the polytrauma patient. The use of rehabilitation equipment, orthotics, prosthetics, and other medical or adaptive devices can sometimes result in complications. Splints used in polytrauma patients to prevent joint contractures can result in pressure ulcers. Compartment syndrome, nerve injury, and infections can develop under casts that are sometimes used to treat contractures in the polytrauma population. An amputee may develop skin irritation, abrasions, ulcerations, or other skin changes from the prosthetic liner or socket.

Definition

Poliomyelitis, also referred to as infantile paralysis, has a special history among infectious diseases. During the first half of the 20th century, there were major epidemics throughout the world. As a viral infection, caused by an RNA virus, it affected mainly children and countries in the Western world with good hygienic and sanitary standards. This occurred when other infectious diseases were being successfully prevented. At the end of the 1940s, several research discoveries led to a better understanding of poliovirus and opened up new opportunities for the manufacture of vaccine. The American organization the March of Dimes invested large sums of money, and the American researcher Jonas Salk started to develop a vaccine, which in 1954 was shown to be effective. General vaccination began in 1956 in the United States and shortly thereafter in other parts of the Western world. This rapidly led to a large reduction in the number of polio cases. In 1988, the World Health Organization decided to try to eradicate polio from the world. The campaign has been highly successful, and there are now only a few countries in Africa (Nigeria) and Asia (mainly Pakistan and Afghanistan) where the virus

still exists. The original goal was that polio should be totally eliminated by 2000, but this deadline has been postponed repeatedly. Today, fewer than a thousand new cases are being reported annually.

It is well known that many polio survivors later in life develop new symptoms, referred to as poliomyelitis sequelae, late effects of polio, or just post-polio. Although sequelae of prior polio have been known since the end of the 19th century, it was not until the early 1980s that researchers came to agree on the term *postpoliomyelitis syndrome* (PPS) to describe the various symptoms that polio survivors may perceive. As there are no accurate statistics describing the number of people being affected by polio, we have no clear account of the number living with PPS. The figures in the literature vary, mostly depending on the definitions used, but it is generally agreed that around 60% of those who initially had paralytic polio will develop PPS [1]. In the United States, it is estimated that more than 1 million survivors of polio live in the country; in the European Union (with a population of approximately 500 million inhabitants), the number is approximated to 600,000 polio survivors. With many young polio survivors in Africa and Asia, it is estimated that up to 10 million people around the world will need health care and rehabilitation during the next decades as a result of their poliomyelitis infection. This makes PPS one of the most common neuromuscular conditions and a challenge to rehabilitation professionals.

PPS is a neurologic disorder characterized by a collection of symptoms occurring decades after the initial paralytic polio. There are different definitions of PPS, but all are more or less based on the original description by Halstead and Rossi in 1985 and consist of five diagnostic criteria (Table 146.1) [2]. At the March of Dimes international conference on PPS in 2000, diagnostic criteria were recommended, including a criterion that symptoms should persist for at least 1 year [3]. Individuals with prior polio may perceive a number of new symptoms, but the three most common are new muscle weakness, fatigue (muscle as well as generalized), and pain from muscles and joints (at rest and during activities). Other, less frequently occurring but equally disabling symptoms are respiratory problems, swallowing problems, and cold intolerance [4,5].

The cause of PPS is not entirely clear, but it is generally agreed that the new symptoms (muscle weakness and fatigue) are due to a distal degeneration of axons in greatly

Table 146.1 Diagnostic Criteria for Postpoliomyelitis Syndrome

- The patient must have had polio.
 - Full or incomplete neurologic and functional recovery must have taken place.
 - A stable period of 15 years must have occurred.
 - Thereafter, two or more of the following health problems must have arisen: lack of stamina/tiredness, muscle or joint pain, recent weakening of muscles in previously known or unknown polio-damaged muscles, recent muscle atrophy, loss of functioning, or intolerance to cold.
 - Symptoms persist for at least a year, and other medical reasons for these increased problems must have been excluded.
- In practice, requirements for typical findings during medical examination and neurophysiologic tests have been added in recent years.

enlarged motor units that develop during recovery after the acute paralytic polio [5]. After the initial paralysis, motor units are enlarged as a compensatory mechanism. These enlarged motor units undergo a continuous remodeling, and at the age of around 50 years, people start to suffer from the “normal” age-related loss of motor neurons [6]. This process of denervation and reinnervation could be accelerated in PPS owing to a premature dropout of motor neurons caused by neuronal damage from the initial infection, increased metabolic demand in the enlarged motor units, or overuse. The loss of whole, enlarged motor units without reinnervation would also contribute and lead to a progressive dropout of muscle fibers. Other reasons underlying PPS have been discussed during the past decades, such as persistent poliovirus infection; overuse weakness due to transition in contractile properties and firing frequency; weight gain; and combined effects of muscle overuse, disuse, and weight gain. On the basis of recent findings of raised concentrations of cytokines in the cerebrospinal fluid, an inflammatory process might also be present as part of PPS [7]. This has led to the development of new treatment strategies that potentially could be beneficial for people with PPS (see the section on treatment).

Regardless of the underlying pathophysiologic mechanisms of PPS, it is a condition that is highly suitable for physicians in physical medicine and rehabilitation. There is no treatment that can cure PPS or any medication that can clearly delay its progression. However, those who have PPS can benefit from taking part in an interdisciplinary comprehensive goal-oriented rehabilitation program to reduce the consequences of the symptoms and the disability that these symptoms impose on their lives [8–10].

Symptoms

Weakness

Muscle weakness typically occurs in muscles involved during the acute infection but may also be experienced in muscles that were not clinically paralyzed originally. There is an association between the initial weakness and weakness occurring later in life. The greater the initial paralysis, the greater is the PPS-related weakness. Most people start to perceive the new weakness around the age

of 50 years; however, the progression of strength losses is usually slow, with an approximate annual loss of 2% to 4% [11]. A history of more rapid progression of muscle weakness during weeks or months could indicate an alternative diagnosis, such as myopathy (e.g., polymyositis, thyroid myopathy), peripheral nerve disorders, or motor neuron disorder (e.g., amyotrophic lateral sclerosis), and should require a thorough investigation.

Fatigue

Fatigue in PPS can be either of muscle origin or more generalized. Muscle fatigue is commonly reported by people with PPS and is characterized by the inability to maintain muscle force. Muscle fatigue is linked to muscle weakness and muscle atrophy, and those with more pronounced muscle weakness also experience more muscle fatigue. Fatigue can also be described as more generalized and of central origin. This type of fatigue can be perceived as severe and persist for several years. It has been found to be associated with reduced physical functioning, increased body pain, reduced sleep quality, and more psychological distress [12]. Typically, this generalized fatigue is described as an influenza-like exhaustion that is often related to the amount of activities performed. Polio survivors usually feel fairly refreshed in the morning and become more fatigued as the day goes on. Some may even complain that they “hit a wall,” sometimes experiencing an almost paralyzing tiredness, and just have to lie down and rest, something that usually relieves the fatigue. It is not unusual for people who have had severe meningitis as part of their acute polio to experience this type of fatigue. In addition, polio survivors who describe a fairly prominent fatigue can also complain about cognitive problems, such as impaired concentration and memory difficulties. Sleep disturbance, which is also reported in polio survivors, can exacerbate general fatigue. As fatigue is an unspecific symptom, commonly occurring in other disorders, alternative diagnoses should be ruled out (e.g., depression, thyroid dysfunction, anemia, other inflammatory diseases, or vitamin B₁₂ deficiency).

Pain

Pain is common among people with PPS and often the symptom that drives them to seek medical help. It has been shown that 50% to 90% of those with PPS experience pain. Pain is common in the shoulders, lower back, legs, and hips and is usually most pronounced in the legs. It is associated with depression and fatigue [13] and can also affect sleep. Not everyone experiences pain, however, and many suffer from mild or no pain. In general, though, increasing pain is related to a lower perceived life satisfaction [14]. Pain can emanate from a joint, a muscle, ligaments, tendons or tendon sheaths, muscle and tendon insertions, and bursae close to a joint. The reason for this is usually the weakness that occurs as a result of muscle atrophy in PPS, which leads to muscle imbalance, stress, and overload and incorrect posture. Pain in PPS can be aching, burning, or cramping in the muscles. Joint pain commonly occurs as a result of the gradual development of osteoarthritis. Osteoarthritis after polio can affect joints in parts of the body with muscle weakness resulting from polio but also affects parts of the body

not affected by polio because of compensatory overload. Osteoarthritis usually occurs in hip, knee, and foot joints. Typical symptoms are pain under strain, but pain at rest is also common.

Respiratory Problems

During the initial polio infection, breathing could be affected as a result of paralyzed respiratory muscles. This was treated with a ventilator for a longer or shorter time, and some have used a ventilator ever since their polio infection, whereas most improved and managed without it. These people may later in life experience new weakness in their respiratory muscles that can lead to an inability to maintain normal carbon dioxide levels in the blood because of reduced breathing volumes. This so-called underventilation is exacerbated by obesity and worsened by other restrictive lung diseases. However, respiratory problems usually occur in less than 10% of those with PPS. People with PPS-related underventilation can complain of morning headache, daytime tiredness, problems with concentration, restless sleep, waking up several times, nightmares, difficulty getting up in the morning, and increased breathlessness during and after exertion.

Swallowing

Swallowing problems occur only in those who had “bulbar” poliomyelitis that affected the swallowing muscles during the initial infection. Usual complaints are feelings of choking, gagging or coughing, and irritation in the throat or a feeling of a lump in the throat. Some people will also complain of voice problems, especially dysphonia [15].

Cold Intolerance

Cold intolerance is a feeling of coldness in the arms and legs and a general inability to thermoregulate. Cold intolerance may be caused by damage to the part of the brain that regulates body temperature, effects on nerves to arms and legs, or reduced muscle mass. It may also be exacerbated by other medical conditions, such as peripheral vascular disease.

Physical Examination

The findings during a clinical, musculoskeletal, and neurologic examination should support the diagnosis of a lower motor neuron disease process. This includes absent or diminished reflexes, decreased muscle tone, and atrophy (symmetric or asymmetric) and weakness of the muscles in the limbs or trunk. Sensory deficits are not part of PPS, but median and ulnar nerve entrapments are common in polio survivors; therefore, it is important to search for symptoms and signs of sensory disturbances in the hands.

Biomechanical symptoms and signs may also occur from musculoskeletal abnormalities in the lower extremities. This, in turn, is a result of contractures due to muscle weakness (hip and ankle), weakness of the quadriceps causing genu recurvatum at the knee, and reduced joint range of motion without apparent contributing weakness (common in the cervical spine and shoulders). Leg length discrepancies are common and may lead to scoliosis and kyphosis and pain from the spinal column.

Manual muscle testing is a quick and useful assessment of function. However, the occurrence and distribution of muscle weakness, as a hallmark of PPS, can be anything from obvious to subtle. It is therefore not always possible to rule out PPS solely by a clinical examination of muscle strength.

Visual assessment of gait and gait disturbances is a starting point for more mechanistic evaluations. Also, specific areas of the body that are reported as painful should be examined. Seating posture, turning, rising from a chair, and stair climbing are specific movements that can be affected, leading to pain, and may require interventions and corrections.

Fatigue is a common symptom and may be associated with other disorders. Therefore it is important to detect possible signs and symptoms of, for example, depression and sleep disorders. Respiratory problems should also be ruled out by a general physical examination complemented by a basic spirometer examination. Assessment of peripheral pulses and edema is also important.

Functional Limitations

Symptoms occurring as part of PPS can affect a person's ability to perform daily tasks, such as dressing, feeding, and grooming, as well as domestic life activities, such as managing one's household, cooking, cleaning, shopping, and participating in leisure activities. This is partly due to a reduced walking ability, including stair climbing, walking shorter and longer distances, and getting in and out of a car. It is also known that these limitations in activities of daily living can affect people with PPS, who may face a variety of challenges related to their participation, which in turn may have an impact on their autonomy and, ultimately, their life satisfaction. Areas that can be affected are family life, social roles, autonomy indoors and outdoors, work, and education [16].

PPS-related muscle and generalized fatigue as well as muscle weakness, muscle and joint pain, and breathing problems could limit the ability to perform usual daily activities, particularly activities that require some physical endurance. This, in turn, can contribute to a general deconditioning, which can cause even greater breathing problems and decreased endurance. It is therefore important to observe signs of a general reduction in physical activity, taking into account all types of daily activities, and to implement a variety of rehabilitation interventions that break this obvious vicious circle.

Diagnostic Studies

Weakness

As part of the routine clinical examination and verification of prior polio, electrodiagnostic studies, including electromyography (EMG) and nerve conduction studies, are highly recommended. Concentric needle EMG is performed to assess the distribution of neuromuscular changes and the degree of changes and also to rule out other neuromuscular diseases. On concentric needle EMG, motor unit action potentials in the limbs previously affected with paralytic polio are abnormally enlarged and polyphasic in configuration, and there is a decreased recruitment secondary to a reduction in the number of motor units available for activation during voluntary muscle contraction [1]. In many cases, EMG may be the only way to determine that signs of PPS are present.

To assess muscle weakness, as part of the routine clinical examination and in planning of appropriate interventions and evaluation, strength testing can be performed. Muscle strength can be assessed manually, with a hand-held dynamometer or with more sophisticated equipment, such as an isokinetic dynamometer. For research purposes, isokinetic dynamometers have been commonly used and are found to be both valid and reliable [17].

If it is clinically needed to establish an alternative or additional diagnosis, imaging of the spine (e.g., magnetic resonance imaging) can help evaluate whether a myelopathy or radiculopathy is present. Useful laboratory studies may include thyroid function studies to rule out thyroid myopathy and muscle enzymes, which can be mildly elevated in PPS.

Fatigue

Persons who experience generalized fatigue should be examined for an alternative diagnosis, for example, anemia, thyroid dysfunction, depression, sleep disorders, and respiratory problems. Other chronic conditions, such as congestive heart failure, diabetes, and chronic infections, can also contribute to fatigue and should lead to appropriate workup. In addition, cancer and other serious malignant diagnoses should also be ruled out.

Pain

For the underlying causes of pain to be understood, various diagnostic procedures are commonly performed, such as blood tests and plain radiographs of the spine and painful joints. Upper extremity neuropathies, such as carpal tunnel syndrome, should be considered and ruled out with electrodiagnostic studies.

Pain in PPS is of nociceptive origin. When pain is of neurogenic origin, alternative diagnoses should be considered, and magnetic resonance imaging and computed tomography can be performed. In rare cases, pain can also occur in persons who have had polio without paralysis or muscle weakness. Last but not least, pain can be due to reasons that are not related to PPS, and it is important that this is also considered.

Respiratory Problems

Respiratory problems can be initially evaluated by a baseline pulmonary function test with a portable desktop spirometer. When a reduced pulmonary function is found, a more thorough investigation with chest radiography and laboratory studies (e.g., arterial blood gas analysis) may be needed, and referral to a pulmonary specialist is recommended.

Swallowing Problems

Swallowing disorders can be diagnosed by imaging studies. A functional endoscopic evaluation of swallowing is most commonly performed.

Cold Intolerance

Cold intolerance can result from several factors, but diagnostic studies are generally not performed unless an alternative diagnosis (e.g., peripheral vascular disease) is suspected.

Treatment

Initial

Weakness

There is yet no treatment that can cure PPS and restore muscle strength. In a series of investigations, different medications (pyridostigmine, amantadine, prednisone, Q10) have been tested, but none has proved beneficial with regard to muscle weakness [18]. On the basis of the notion of an inflammatory process in the central nervous system of patients with PPS, intravenous immune globulin has been tested. In two larger randomized controlled trials, variable effects on muscle strength, pain, physical activity, and quality of life have been described [19,20]. The effect on muscle strength is, however, generally small and within the limits of random variability that would be seen from just repeated measurements [17]. However, the effect on other variables is more prominent. One clinically uncontrolled study showed that two thirds of 45 patients with PPS and pain reported a decrease on the visual analog scale for pain after treatment and 40% reported a decrease of more than 20 points [21]. A follow-up study of 41 patients [22] from the previous treatment trial [19] showed that scores of the physical component of the Short Form 36 (bodily pain and vitality), the visual analog scale for pain, and the 6-minute walk test were significantly better at 1 year compared with baseline and control subjects. These findings encourage further controlled trials to more firmly establish whether this treatment should be used in PPS.

Fatigue

Fatigue is managed by a multimodal approach. Primarily, any medical condition that may be contributing to it should be treated. Sleep disorders, depression, and other causes should be appropriately treated. Proper sleep hygiene is important (e.g., regular bedtimes, avoidance of caffeine late in the day); depression can be treated with medication or counseling or both. It is also important to address a person's daily activities; various fatigue management interventions, including pacing and taking rest breaks during the day, can be taught. The use of medication to treat fatigue has not been highly successful. Intravenous immune globulin has shown some promising results on fatigue and vitality in subgroups of fatigued patients with PPS [23]. More recently, modafinil has been used to treat fatigue pharmacologically; in more controlled studies, the results have not been particularly encouraging [24], whereas in clinical practice and individual cases, the medication may have an effect. The dose usually starts at 100mg orally every morning and may be increased to 200mg daily, 100mg in the morning and 100mg at lunchtime.

Pain

Treatment of pain should always start with a thorough analysis of the underlying cause and thereafter selection of appropriate interventions. Treatment of joint pain consists mainly of movement training (e.g., pool exercise) in combination with mobility aids, other aids, or orthotic devices. Transcutaneous electrical nerve stimulation, acupuncture, nonsteroidal anti-inflammatory drugs, and cortisone injections are other alternatives. Other medications, such as paracetamol and tramadol, can also be prescribed. In severe

cases of osteoarthritis, joint replacements are necessary, which may then eliminate the pain completely.

Pain near joints (in tendons and ligaments) is usually due to a continuous overload as a result of muscle weakness. Polio survivors often need mobility aids to relieve this pain when they walk, stand, or engage in other activities. It is also important that they be given information on the importance of reducing the load on their bodies. Activity-related muscle pain is often caused by overuse of the weakened musculature. The most important part is to focus on the reason for the muscle pain. As it is often due to overuse of muscles, the person with PPS needs to understand this so that he or she can make necessary lifestyle changes. This is combined with the prescription of mobility aids to reduce overload during various activities, the provision of information about changed activity patterns, the correction of a sitting position, and the prescription of orthotic devices. Normally, pain is reduced when the load is reduced, but if the overuse continues, the pain can become more lasting and spread to the whole body. Postpoliomyelitis myalgias can be treated and have been reported to respond to low-dose tricyclic antidepressants and also to gabapentin and pregabalin.

Respiratory Problems

Respiratory problems, particularly sleep apnea, are often treated with significant improvement in symptoms by continuous positive airway pressure or bilevel positive airway pressure at night.

Swallowing Problems

Swallowing problems are treated conservatively, with specific recommendations from a speech and language pathologist.

Cold Intolerance

Cold intolerance is treated symptomatically, and recommendations to wear layered clothing, thermal underwear,

and wool socks are given. Electrically heated stockings and insoles can also be tried.

Rehabilitation

Interdisciplinary rehabilitation is the cornerstone of appropriate management in PPS [25]. Several aspects of life are often affected, so it is important that the rehabilitation team have a thorough understanding and experience of PPS. Rehabilitation in PPS can be described as a process of change. In a qualitative study, the experiences of 12 persons with PPS who had participated in an individualized, goal-oriented, comprehensive interdisciplinary rehabilitation program were presented [26]. The focus of the program was to reduce self-perceived disability by providing a variety of interventions and thereby to maximize each individual's physical, mental, and social potential. The rehabilitation program was experienced as a turning point in the participants' lives (Fig. 146.1). Before rehabilitation, they felt that they were on a downward slope without control. Rehabilitation was the start of a process of change whereby they acquired new skills that, over time, contributed to a different but good life. After approximately a year, they had a sense of control and had accepted life with late effects of polio. They had also established new habits, had taken on a changed valued self, and could look to the future with confidence. The participants experienced the benefits of the program developed by an ongoing and iterative process that took at least a year to complete. This emphasizes that the outcome of a PPS rehabilitation program should be assessed from a long-term perspective. The results also indicate that the effect of an interdisciplinary rehabilitation program goes beyond that of simply reducing impairments. This, in turn, emphasizes the need to select outcome measures that address the impact of rehabilitation programs in a broad sense. One newly developed rating scale that specifically assesses self-reported impairments has been presented [27]. This scale, Self-reported

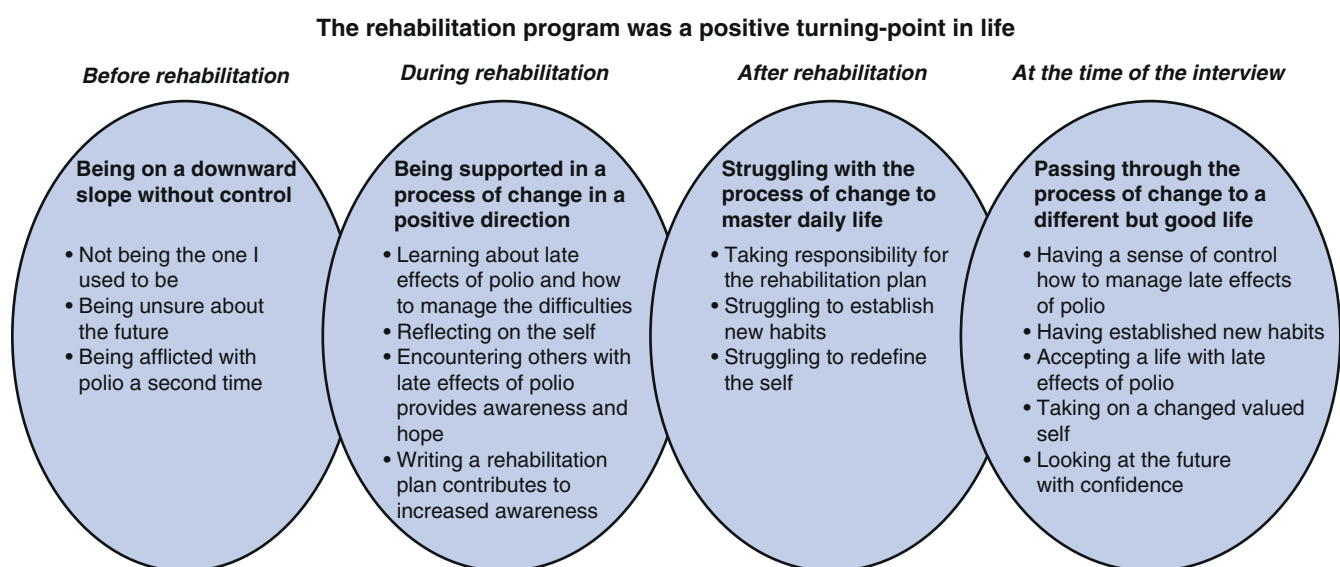

FIGURE 146.1 The core category, with the four categories and their subcategories, describing the experiences of persons with postpoliomyelitis syndrome and the influence of an individualized, goal-oriented, comprehensive interdisciplinary rehabilitation program. (From Larsson Lund M, Lexell J. A positive turning point in life—how persons with late effects of polio experience the influence of an interdisciplinary rehabilitation program. *J Rehabil Med* 2010;42:559-565.)

Impairments in Persons with late effects of Polio (SIPP), has been shown to have good psychometric properties and will facilitate the evaluation of impairments that people with PPS may experience.

Positive effects of rehabilitation were also reported in a pilot study of 27 participants with PPS. Significant improvements were noted for exercise endurance, depression, and fatigue but not for muscle strength and anxiety [28]. Another uncontrolled study found similar effects up to a year after multidisciplinary rehabilitation with emphasis on physiotherapy [29].

During a rehabilitation program, persons with PPS will be assessed by different team members and various interventions will be planned. Family members should also be encouraged to take part in the program. Many interventions cannot be evaluated until the person has actually tried them at home and later returns for follow-up. Examples of such interventions are prescription of mobility aids (scooter or power wheelchair), orthotic devices, and other adaptive equipment; teaching of compensatory techniques; medical and nonmedical interventions aimed at reducing pain, fatigue, and sleep disturbances; therapeutic home exercises, ergonomics, and vocational interventions to maintain workability; and home visits to assist in making appropriate environmental adaptation and driving adaptations [8–10]. It is therefore important that outcomes be assessed not only directly after a short rehabilitation period but also after the participants have been able to evaluate the different interventions in their preferred environment.

The exercise program should always be individualized and address flexibility, strength, and conditioning. The frequency, duration, and intensity depend very much on the distribution of PPS-related muscle weakness. For parts of the body and muscles that are not affected or only mildly affected, there are generally no restrictions. Exercise such as resistance training as well as an endurance type of training can be prescribed and may affect fatigue and quality of life positively [30]. On the other hand, whole-body vibration, a method that has gained popularity in the past decade, had no effect on muscle strength and gait performance [31]. When body parts and muscles are significantly affected by PPS, nonfatiguing protocols are preferred and the intensity of exercise must be individually tailored. EMG can often be used to decide on the type of activity, the frequency, and the duration. Non-weight-bearing exercises, such as pool exercise or cycling, are usually well tolerated, whereas high-impact exercises, such as jogging, may exacerbate pain and should be performed with caution. Appropriate prescription of orthotic devices will enable many polio survivors to walk, transfer, exercise, and function optimally within their limitations. Today, there are a variety of bracing options and materials, far from the heavy ones prescribed decades ago. Therefore, lightweight options, such as carbon fiber and Kevlar, should always be considered for this population.

Procedures

On occasion, therapeutic procedures are recommended on the basis of specific symptoms. Musculoskeletal symptoms may be treated with local steroid injections (e.g., tendinitis, osteoarthritis in the foot joints).

Surgery

Surgery should not be avoided when a disabling osteoarthritis is present. Joint replacements and carpal tunnel release can be successfully performed.

Potential Disease Complications

An important complication in PPS is falling, because of weakness and mobility problems, with subsequent injury (e.g., fracture or traumatic brain injury), and many persons with PPS complain about falls and a fear of falling [32]. Because of reduced bone mineral density, osteopenia, or osteoporosis in affected limbs, polio survivors may be more susceptible to fracture. Therefore bone mineral density studies should be considered in polio survivors with prominent weakness. Oral bisphosphonate treatment has led to significant increases in bone mineral density at the hip of PPS patients, which may have a protective effect on fracture risk [33]. Swallowing difficulties and respiratory problems can lead to pneumonia or aspiration. Also, polio survivors may be more prone to cardiovascular diseases [34], and therefore a general screening for cardiovascular risk factors in individuals diagnosed with PPS is recommended.

Potential Treatment Complications

Treatment complications may occur as a result of medication side effects and inappropriate interventions. Analgesics and nonsteroidal anti-inflammatory drugs have well-known side effects that most commonly affect the gastric, hepatic, and renal systems. Tricyclic antidepressants have cholinergic side effects, the most serious of which is the possibility of acute urinary retention in men (men with underlying prostate problems are generally at risk). Antihypertensive drugs such as beta blockers could potentially reduce muscle strength, and alternative medication for increased blood pressure should be considered. Statins can have a deleterious effect on muscle [35], which should be taken into account when they are prescribed. Polio survivors are reported to take longer to recover after general anesthesia and may require larger than the usual doses of postoperative pain medication. Careful consideration should therefore be given to the risks and benefits of surgery for this population.

During rehabilitation interventions, caution must always be used when someone's gait and mobility are altered, such as with use of an orthotic device. Too strenuous exercises could exacerbate weakness and fatigue and increase the risk for falls.

CHAPTER 147

Postconcussion Symptoms

Mel B. Glenn, MD
Seth D. Herman, MD

Synonym

Postconcussive disorders

ICD-9 Code

310.2 Postconcussion syndrome

ICD-10 Code

F07.81 Postconcussional syndrome

Definition

Postconcussion symptoms are a set of symptoms commonly seen after concussion. The term *concussion* is generally used as a synonym for mild traumatic brain injury (mTBI). A number of definitions with varying lower and upper limits of severity for diagnosis have been proposed [1]. One commonly used definition of mTBI is a traumatically induced physiologic disruption of brain function, manifested by at least one of the following:

- any period of loss of consciousness;
- any loss of memory for events immediately before or after the accident;
- any alteration in mental state at the time of the accident (e.g., feeling dazed, disoriented, or confused); and
- focal neurologic deficits, which may or may not be transient;

but in which the severity of injury does not exceed the following:

- loss of consciousness of approximately 30 minutes or less;
- after 30 minutes, an initial Glasgow Coma Scale score of 13-15; and
- post-traumatic amnesia not longer than 24 hours [1].

“Complicated” mTBI is characterized by the addition of intracranial abnormalities on computed tomography (CT) scan on the day of injury [2].

There are also several classification systems [3]. Table 147.1 presents a classification established by the American Academy of Neurology [4].

Bazarian and colleagues [5] reported the incidence of emergency department visits for mTBI to be 503 per 100,000, which is about 1.4 million emergency department visits for mTBI in the United States per year. This is similar to the Centers for Disease Control and Prevention estimate of 1.375 million [6]. However, the true numbers are probably considerably higher, given that a large percentage of people do not seek hospital treatment.

Symptoms

The most common postconcussion symptoms are headache, dizziness (often vertiginous) or poor balance, forgetfulness, difficulty in learning or remembering, difficulty in concentrating, slowed thinking, hypersomnolence, fatigue, insomnia, depression, anxiety, irritability, sensitivity to noise and light, and visual problems [7,8]. The most commonly used instrument for assessing the number and severity of postconcussion symptoms is the Rivermead Post-Concussion Symptoms Questionnaire, which has been found to have adequate divergent validity and reliability [9-11]. Criteria for “postconcussion syndrome” have been established by the *International Classification of Diseases, Ninth Revision* [12], the *International Statistical Classification of Diseases and Related Health Problems, Tenth Revision* [13], and the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* [14]. However, symptoms may be present in a wide variety of both limited and extensive constellations and as such do not constitute a true syndrome [7,8]. There may be a lag of days or weeks between the concussion and the patient’s first complaints, and some related phenomena, such as depression, may not become manifest until months after the initial injury. Although these symptoms can be seen with any severity of injury, they are often most pronounced in the context of mTBI. Over time, most people make a complete clinical recovery [11]. Although some authors have estimated that less than 5% still have symptoms 1 year after injury [15], studies vary considerably in this regard [16-18]. The prevalence of postconcussion symptoms is relatively high in healthy populations [15]; in people with whiplash and other painful conditions, depression, post-traumatic stress disorder (PTSD), and acute stress; and in

Table 147.1 American Academy of Neurology Classification of Mild Traumatic Brain Injury

Grade of Concussion	Characteristics
Grade 1	Transient confusion All symptoms <15 minutes and Mental status changes <15 minutes
Grade 2	Transient confusion Any symptoms >15 minutes and/or Mental status changes >15 minutes
Grade 3a	Brief loss of consciousness (seconds)
Grade 3b	Prolonged loss of consciousness (minutes)

From Practice parameter: the management of concussion in sports (summary statement). Report of the Quality Standards Subcommittee. *Neurology* 1997;48:581-585.

people litigating non-head injuries [19]. Nevertheless, one study found a difference of 31% between those who had mTBI and a non-head-injured control group with orthopedic injuries with respect to the number who had three or more symptoms 1 year after injury. However, these differences were significant only among those who were married and those who had higher levels of education [17].

The etiology of postconcussion symptoms is often multifactorial, and much of it is still not well understood. The usual inciting factors are mTBI with residual impairment of cognition, whiplash or other soft tissue injury to the head and neck, and at times disruption of the vestibular apparatus or central vestibular insult. Problems with attention, forgetfulness, and fatigue coupled with the frequent development of headaches, insomnia, and vertigo often lead to considerable anxiety and depression and a “shaken sense of self” [20]. In those who have persistent problems, a complex of symptoms often feed one on the other [7], exacerbating the cognitive impairment, which may then take on a life of its own even as the underlying brain injury continues to recover [20,21]. A common scenario is one in which pain, anxiety (including, at times, PTSD), and depression contribute to insomnia, which in turn exacerbates headaches, and all of these symptoms contribute to cognitive impairment [11]. Early on, as the symptoms attributable to brain injury gradually improve, the patient may not experience any cognitive improvement because other factors are driving these symptoms. The lack of improvement often increases the patient’s anxiety and can bring about depressive feelings. A vicious circle ensues (Fig. 147.1). Difficulty in concentrating can also result in headaches, which exacerbates the complex. PTSD should be suspected in individuals who have reexperiences of the original injury (“flashbacks”), avoidance of situations similar to that which caused the injury (e.g., riding in a car), a feeling of emotional “numbness,” and hyperarousal. There are high prevalence rates of PTSD, mTBI, and their co-occurrence in recently deployed soldiers [5].

There is evidence to suggest that persistence of symptoms is associated with a high number of early symptoms: acute headache, multiple painful areas, nausea, dizziness, or balance problems; early impaired memory; intoxication at the time of injury; intracranial lesions on the day of injury

FIGURE 147.1 A possible postconcussion scenario: relationship between brain injury, emotions, pain, insomnia, and cognitive recovery.

CT scan; loss of white matter integrity on diffusion tensor imaging; preexisting social, psychological, and vocational difficulties; lack of social support; less education; lower socioeconomic status; age older than 40 years; being married; female gender; current student status; litigation or compensation; being out of work secondary to injury; motor vehicle crash as cause of injury; lack of fault for a collision; preexisting physical impairment; APOε4 genotype; and preexisting brain (including prior mTBI) and other neurologic problems. Studies vary with respect to some of these findings [8,11,15,22–26]. However, the total body of evidence regarding the causes of poor outcome after mTBI suggests a complex interaction among biologic, psychological, and social factors, with different factors varying in significance by the individual [27]. It is notable that people with mTBI have been found to underestimate the frequency of symptoms that they had *before* the injury, demonstrating a bias toward attributing current symptoms to the mTBI (“good old days bias”) [17].

Most authors have not defined a particular time frame for the designation of “persistent” postconcussion symptoms; those who have done so have used 3 months as a cutoff [16,28]. The question of persistence of cognitive impairment after mTBI has been a subject of considerable controversy. Most controlled studies and meta-analyses indicate that cognitive deficits found on neuropsychological testing resolve within 3 months of mTBI, with the notable exception of complicated mTBI [2,29]. Most studies have been done with relatively young people, often athletes. Some studies have found subtle differences from controls [30,31] or differences on more demanding tests, such as dual-task performance, months or years after injury [32]. Subtle differences in balance have also been found among college football players who have had one or more concussions compared with those who have not [32]. Athletes who have had multiple concussions have been found to do worse on neuropsychological testing than controls [22,33]. There is a greater prevalence of mild cognitive impairment in later life [34] among professional football players who have had concussions than among those who have not had a concussion. These findings suggest that a single concussion may result in some loss of brain function, possibly subclinical in most people. In addition, individuals who have had one or more concussions months or years ago have been found to have evidence for loss of white matter integrity on diffusion

tensor imaging [26] and differences from control subjects on functional magnetic resonance imaging (fMRI) [35] and event-related potentials [32].

Cognition

The patient should be questioned about the inciting event with regard to whether there was a loss of consciousness, loss of anterograde or retrograde memory, other alteration in mental status, or focal neurologic findings. A patient's subjective feeling of being dazed or confused may or may not reflect actual brain injury. It is common for people to feel dazed because of the emotional shock experienced after an accident. There is often limited or no documentation of the details of the patient's mental status immediately after the accident, and a clinician must do his or her best to reconstruct the situation largely on the basis of the history given by the patient. The observations of others may help clarify whether the patient was responding slowly or otherwise appeared confused. Emergency medical records should be obtained whenever possible but may or may not reflect the patient's mental status at the scene of the accident and may not pick up more subtle deficits if only orientation is evaluated.

Headaches

Tension, migraine, cervicogenic (musculoskeletal), and mixed headaches are the most frequent types seen after concussion. Pain from soft tissue injury at the site of impact, occipital neuralgic pain, and dysautonomic cephalgia can be seen as well. The patient should be questioned with respect to severity, quality, location and radiation, date of onset, duration, frequency, exacerbating or ameliorating factors, and frequency of medication use in addition to associated symptoms, such as nausea, vomiting, visual phenomenon, diaphoresis, rhinorrhea, and sensitivity to light and noise [36,37].

Vestibular/Balance Disorder

Vertigo and other illusory motion related to head movement or position as well as impaired balance can be caused by cupulolithiasis or canalolithiasis (benign paroxysmal positional vertigo), brainstem injury, migraine-associated vertigo, labyrinthine concussion, or perilymph fistula or may be cervicogenic. Perilymph fistula and labyrinthine concussion are usually associated with hearing loss and tinnitus as well. Nonvertiginous dizziness is not usually directly related to concussion; medication-induced dizziness (e.g., by nonsteroidal anti-inflammatory drugs and antidepressants) and other causes should be considered, including psychogenic dizziness [38]. See also Chapter 8.

Sleep

A history of fatigue or daytime sleepiness should suggest the possibility of a sleep disorder. Delayed sleep phase syndrome and disrupted sleep-wake cycles can usually be diagnosed by history. Being overweight or obese or heavy snoring suggests obstructive sleep apnea. Difficulty in falling asleep and maintaining sleep can be determined by history [11].

Other

The physician's history of the events surrounding the initial accident should also include exploration of other associated injuries, seizure, vomiting, and drug or alcohol intoxication. A preinjury medical, social, psychological, vocational, and educational history should be obtained, including any history of attention deficit disorder or learning disability.

Physical Examination

Cognition

The examination of the individual with postconcussion symptoms will often elicit problems with attention, memory, and executive function on mental status evaluation. Memory problems are most often related to attention deficits or difficulty with retrieval [39]. The contribution of attention, encoding, and retrieval problems to verbal memory can be evaluated with the presentation of a word list followed by immediate recall, recall after 5 minutes, and then a multiple choice recognition task, which provides the structure needed to assist retrieval when information has been encoded. The Montreal Cognitive Assessment, which contains subtests that challenge executive function as well as memory and attention, is a useful tool to assess for cognitive impairment, although it has not been studied in traumatic brain injury [40]. However, findings on mental status testing may be normal; more extensive evaluation by neuropsychological testing, including reaction time [31] and continuous performance tasks, may be necessary to reveal the deficits. Findings inconsistent with daily functioning or more severe than would be expected for someone with mTBI indicate that there may be poor effort or other contributing factors [19,41]. See the section on differential diagnosis for potential contributing factors [20].

Psychological

Assessment of affect, demeanor, and behavior may reveal evidence of depression, anxiety, and other psychological characteristics. The Patient Health Questionnaire-9 is one approach to assessing depression. It is a brief questionnaire that mirrors the diagnostic criteria of the *Diagnostic and Statistical Manual of Mental Disorders* (fourth edition) for major depression. It has been found to be valid and reliable in people with traumatic brain injury [42]. The Primary Care PTSD Screen is another useful instrument. Those who screen in for PTSD should then receive a more thorough assessment [43].

Headaches

Examination of the head and neck often elicits restriction of motion, tender points, or trigger points radiating to the head. There may be tenderness at the site of the original head injury and occasionally pain elicited by compression of the occipital nerves [36,37]. See Chapters 102 and 105.

Vestibular/Balance Disorder

During acute vertigo, nystagmus will often be present, generally stronger with peripheral than with central vertigo.

As adaptation begins to occur, nystagmus may be seen only with certain maneuvers (e.g., after 20 horizontal head shakes) or may not be seen at all. When benign paroxysmal positional vertigo is the cause, the Hallpike-Dix maneuver is usually positive. This maneuver is performed from the sitting position on a flat surface with the head rotated 45 degrees to either side. The patient is quickly lowered from the sitting to the lying position, until the head, still rotated, is extended over the edge of the examining table. Vertigo is experienced and nystagmus seen after a lag of up to 30 seconds [38]. Neck range of motion and tender points or trigger points should be assessed for contributions from cervicogenic dizziness (see also Chapter 8). Patients with vertigo and other illusory movement may also have balance problems, but impaired balance with difficulty on tandem walk, standing on one leg, hopping, and other maneuvers may be seen without vertigo. The Balance Error Scoring System can provide a quantifiable assessment of balance [11].

Visual

Some patients complain of a feeling of visual disorientation or intermittent blurred vision. The symptoms can be related to a need for changes in refraction, accommodative dysfunction [44], or vascular, vestibular, attentional, or psychological problems. Frequently nothing will be found on routine examination.

Olfactory

The sense of smell may be affected by damage to branches of the olfactory nerve as they pass through the cribriform plate or by focal cortical contusion.

Other cranial nerve testing, muscle strength, cerebellar testing, deep tendon reflexes, plantar stimulation, and sensation are usually normal.

Functional Limitations

The extent to which postconcussion symptoms interfere with function varies with the extent of the associated pathologic process but depends also on the psychological reaction to the postconcussion impairments. The most common consequences of postconcussion symptoms are limitations in home and community living skills or social, academic, or vocational disability. Patients may be forgetful and inattentive, may have difficulty following conversations, and may find crowded, noisy environments difficult to tolerate. Headaches are often exacerbated by attentional demands and other stresses and may themselves contribute to inattentiveness. Vertigo or other illusory motion causes difficulty in tolerating motion, including, for some, moving vehicles, and may be associated with balance problems. Depression, anxiety, and irritability can contribute heavily to functional limitations.

Diagnostic Testing

The brain CT scan is the standard for the acute assessment of intracranial lesions after mTBI [45]. Indications for emergent CT scan include headache, vomiting, loss of consciousness or amnesia, alcohol intoxication, age older

than 60 years, post-traumatic seizure, physical evidence of trauma above the clavicles, and current anticoagulant use [45,46]. Although definitive criteria have not been established for those who have had no loss of consciousness, it is probably wise to obtain a CT scan or MRI study for anyone who continues to have frequent headaches, severe lethargy, confusion, or anterograde memory loss or who has focal neurologic findings and has not had any neuroimaging acutely. MRI with susceptibility-weighted imaging is more likely to show microhemorrhage related to diffuse axonal injury [26]. Event-related potentials [32], serum biomarkers (such as S100B [47]), advanced magnetic resonance techniques (such as diffusion tensor imaging [26] and fMRI [35]), and metabolic imaging (such as positron emission tomography, single-photon emission computed tomography, and magnetic resonance spectroscopy [48]) have shown promise but have not yet been studied thoroughly enough to be used routinely to answer clinical questions after mTBI [49].

Cervical spine radiographs should be obtained for patients with significant neck pain shortly after the accident to assess for fracture or subluxation.

Neuropsychological evaluation should be performed if cognitive deficits persist, particularly when rehabilitation therapies are to be pursued. Testing can provide the patient and the treatment team with a more thorough understanding of the patient's neuropsychological strengths and weaknesses and in some instances can assist with understanding of the interplay between neurocognitive and other psychological contributions to cognitive disturbance. Tests for assessment of malingering and symptom magnification ("effort testing") can be incorporated when necessary. In one study, people with mTBI for whom financial compensation was available, and who were referred for neuropsychological testing an average of 19.4 months after injury, had a 26.7% failure rate for effort testing (Test of Memory Malingering). Those with better benefits had a higher rate than those with modest benefits [50]. However, symptom magnification does not eliminate the possibility that the person has real cognitive deficits as well. It is useful for sports teams to have their players undergo at least a brief baseline cognitive testing or, if the resources are available, formal neuropsychological testing so that any changes can be identified after the concussion [51]. A history of attention deficit/hyperactivity disorder or learning disability, certain medications or abused substances, depression, anxiety, pain, sleep disorders, malingering, symptom exaggeration, and even expectation of the cognitive effects of mTBI can lower test performance [52]. On the other hand, normal findings on testing do not preclude a more subtle but significant underlying cognitive impairment.

A sleep study (polysomnography) is indicated to rule out sleep apnea and other disorders when excessive daytime sleepiness does not improve despite the absence of sedating medications. The threshold for obtaining polysomnography should be lower for overweight or obese patients or those who snore prominently. When vestibular complaints are prominent or are not improving in the early months after the injury, a thorough vestibular evaluation, including electronystagmography, may be indicated. Audiologic evaluations should be done when hearing loss is suspected or when tinnitus persists [38]. Ophthalmology or optometry evaluation by someone with particular expertise in visual problems related

to brain injury should be considered when visual symptoms are present. Although post-traumatic neuroendocrine dysfunction is more commonly found among those with more severe traumatic brain injury, even mTBI may be associated with pituitary dysfunction. Schneider and coworkers [53] found a prevalence of endocrine disorders of 16.8% among patients with mTBI and persistent postconcussion symptoms. Neuroendocrine testing should be considered in individuals with mTBI who have persistent fatigue, cognitive difficulties, behavioral changes, or depression as these can be symptoms of post-traumatic hypopituitarism. Other manifestations include decreased libido, amenorrhea, myopathy, and life-threatening complications such as sodium dysregulation and adrenal crisis [54]. Recommended screening includes serum free thyroxine, thyroid-stimulating hormone, morning cortisol, prolactin, and insulin-like growth factor 1 levels; testosterone concentration in men; and follicle-stimulating hormone concentration in postmenopausal women or premenopausal women with amenorrhea [55].

Differential Diagnosis [11,23]

Depressive disorders
Anxiety disorders, including post-traumatic stress disorder
Somatoform disorder
Whiplash injury with associated headache (myofascial pain syndrome)
Other chronic pain
Insomnia
Sleep apnea
Endocrine disorders
Other medical illness
Substance abuse
Prescription medications
Early progressive dementias
Malingering and symptom magnification

Treatment

Initial

Treatment will depend on the specific constellation of symptoms and their severity. In general, if the patient

is seen in the first few weeks after the injury, the major emphasis should be placed on caring for acute problems with headache, neck pain, and insomnia as these symptoms tend to be more responsive to early treatment than cognitive impairment and dizziness. However, education of the patient and significant others is the most important early intervention. Explanations should integrate the physical, cognitive, and psychological dimensions of the symptoms in as clear and simple a manner as possible. This is no small task, given the diversity of symptoms and possible causes and our limited understanding of postconcussion disorders at this time. Some patients are very sensitive to discussions of psychological etiology and may not return if they believe that this has been overemphasized. The patient's experience, including the psychological reactions, should be validated and normalized [20]. The patient should be told that improvement is to be expected, and after concussions without high-risk factors (e.g., numerous previous concussions, complicated mTBI), reasonable reassurance should be given that a good recovery is likely without dismissing what the patient is experiencing. Establishing a reasonable expectation for recovery can be helpful in preventing postconcussion symptoms [56,57]. Anticipating the psychological reactions to postconcussion symptoms that occur in some patients allows the patients to recognize these reactions if they begin and leaves the door open for them to seek psychological help. Follow-up should be planned and more extensive counseling provided at the first signs of significant distress. Patients with significant symptoms should be instructed to take time off from work, school, or other taxing activities as the attentional demands and accompanying psychological stresses of attempting to perform under these circumstances can exacerbate the symptoms [23]. All patients should be instructed not to drive for at least the first 24 hours, longer when they have had post-traumatic seizures, slow processing speed, attention deficits, dizziness, and visual or other symptoms that are likely to interfere [11].

Athletes should not go back to competitive sports on the day of injury until they are free of symptoms and have gone through a program of graded exertion symptom free. Those with more severe concussions should move through this program more slowly [51]. Refer to Table 147.2 for guidelines for the stepwise return to sports activities.

Table 147.2 Template for Stepwise Return to Sports

Stage	Activity	Objective
No activity	Symptom-limited physical and cognitive	Rest and recovery
Light aerobic exercise	Walking, swimming, or stationary bicycle, keeping intensity less than 70% of maximum predicted heart rate; no resistance training	Modest increase in heart rate
Sport-specific exercise	Skating drills in ice hockey, running drills in soccer; no head impact activities	Further increase in heart rate in sport-specific context
Noncontact training drills	Progression to more complex training drills (e.g., passing drills in football and ice hockey); may start progressive resistance training	Challenge agility, coordination, and cognitive aspects of sport
Full-contact practice	Following medical clearance, participate in normal training activities	Full physical and cognitive challenge; restore confidence and allow coaching staff to assess functional skills
Return to play	Normal game play	

Modified from McCrory P, Meeuwisse W, Johnston K, et al. Consensus statement on concussion in sport—the 3rd International Conference on Concussion in Sport held in Zurich, November 2008. *PM R* 2009;1:406-420.

Severe acute vertigo may require a few days of bed rest [38], but only if it is absolutely necessary. The management of acute neck pain is described in Chapter 6.

Rehabilitation

Cognition

If symptoms persist, patients may benefit from speech or occupational therapy to learn strategies for compensating for problems with arousal, attention, memory, and executive function and, later, training for internal compensation and restoration of cognitive skills [58–61]. The timing of therapies depends on the severity of the disability and the pace of recovery, which can often be determined within the first 3 months after injury. There are no published data on the optimal timing of these interventions, and no specific guidelines are available. Therapies should address the specific functional tasks that the individual faces on a daily basis and may need to include community outings. Foam earplugs or sunglasses can be tried for those sensitive to noise and light, respectively. Paper or electronic memory aids may be helpful. Psychostimulants and dopaminergic drugs (e.g., methylphenidate, amphetamines, atomoxetine, donepezil, modafinil, armodafinil, amantadine) and cholinesterase inhibitors (e.g., donepezil, 5–23 mg daily) that treat attentional and arousal disorders may be useful for reducing the extent of attention deficits and underarousal [62,63]. When sleep apnea is contributing to cognitive problems, positive airway pressure therapy, sleep position changes, or custom dental devices are indicated. Both resistance and aerobic exercises can result in improved cognitive function [64,65]. Exercise may also benefit other postconcussion symptoms when heart rate is kept below the rate that provokes symptoms [66]. There is some evidence to suggest that acupuncture may also result in improved cognitive function [67].

Psychological

If symptoms persist beyond a few months, psychological counseling is almost always indicated. Some individuals benefit from learning relaxation techniques and sleep hygiene. Cognitive-behavioral therapy focused on sleep issues can help insomnia [68]. Education of the patient and significant others should continue to emphasize the interaction between the cognitive, psychological, and physical sequelae. It is important that the rehabilitation team communicate on a regular basis for treatment planning and to ensure that all clinicians approach these issues from a common framework so that mixed messages are not delivered to the patient. Support groups are often useful as well and offer an opportunity for further education about the various contributing factors. Cognitive-behavioral therapy can be helpful in concert with other treatments [69] even when symptoms do not seem to be explained by the medical condition [70]. It can target depression, anxiety, insomnia, pain, and probably other postconcussion symptoms as well. Other psychotherapy approaches include acceptance and commitment therapy and self-management, both of which focus on improving daily function rather than on improving symptoms [52]. Family counseling should be offered when there is evidence of significant stress on family members or problem family dynamics.

Depression and anxiety can also be addressed pharmacologically when they are severe and prolonged, contributing

to cognitive impairment, or interfering with progress in rehabilitation, usually after or simultaneously with counseling interventions. It is generally best to begin with non-sedating, nonanticholinergic agents, such as the selective serotonin reuptake inhibitors (e.g., sertraline), to avoid further exacerbation of neuropsychological problems [62]. Cognitive status has been found to improve after treatment with sertraline [71]. Sedating agents, such as trazodone, zolpidem, or eszopiclone, may be necessary for those with significant insomnia [62] if treatment of depression and anxiety and sleep hygiene approaches are not successful. Zolpidem (10 mg at bedtime) can cause cognitive impairment in the morning [72]. Melatonin (0.5–3 mg) can be helpful, especially with delayed sleep phase disorder.

Headaches

Post-traumatic headaches can have a number of different causes and may be multifactorial [21,23,24,36–38]. They are therefore best addressed on multiple levels, with the emphasis depending on the headache type [73]. Treating problems with attention, sleep disorders, and psychological stresses may reduce the tension component of headaches. Relaxation techniques, including electromyographic biofeedback, can be taught. When myofascial pain originating in the neck, upper back, or temporomandibular joints contributes, physical therapy including stretching and strengthening exercises, postural retraining, environmental modification, trigger point massage, modalities, electromyographic biofeedback, or massage should be tried. However, headaches often persist despite these interventions. Trigger point, facet joint, and other injections can be helpful, as can acupuncture and pharmacologic approaches. Patients with temporomandibular joint problems can be treated with myofascial techniques, mouthguards, and exercises.

Those headaches that fit the criteria for migraine headaches may respond to acetaminophen, nonsteroidal anti-inflammatory drugs, or vasoconstrictive agents commonly used to abort migraine headaches (e.g., sumatriptan). Overuse of these agents can cause rebound headaches. For prophylaxis, anticonvulsants (particularly gabapentin and valproic acid), beta blockers (e.g., propranolol), calcium channel blockers (e.g., verapamil), and antidepressants (e.g., amitriptyline, nortriptyline, fluoxetine, venlafaxine) can be helpful. Topiramate often provides some relief but causes too much cognitive decline to be used as a first-line drug [74]. However, if it relieves frequent headaches that themselves are causing cognitive impairment, the tradeoff may be favorable. Tension headaches may respond to some of these agents as well, although not to calcium channel blockers. Injection of local anesthetics or corticosteroids can be considered for greater or lesser occipital neuralgia that does not respond to more conservative approaches. Injection should be done at the site along the nerve that replicates the headache when it is palpated [36,73] (see Chapter 102).

Vestibular/Balance Disorder

When vestibular symptoms persist beyond 3 months, vestibular rehabilitation may both encourage central nervous system accommodation under controlled circumstances and assist the patient in learning compensatory strategies [75]. Canalith repositioning maneuvers may bring relief from benign paroxysmal positional vertigo by displacing

and dispersing calcium stones [76]. Suppressive medications (e.g., clonazepam, scopolamine, meclizine) should be used judiciously, if at all, when other approaches have failed [38]. The evidence for their efficacy is not strong, and they can cause worsening of problems with attention and memory. Frequent vertigo or other illusory motion in people with migraine headaches (migraine-associated vertigo) is best treated preventively with tricyclic antidepressants, beta blockers, or calcium channel blockers and vestibular rehabilitation. Cervicogenic dizziness can be treated by addressing the underlying cervical musculoskeletal problems (see Chapter 8). Physical therapy can help improve balance.

Vocational

The extent to which an employer or academic institution is supportive after mTBI can be crucial to successful return to work for those with persistent postconcussion symptoms. Vocational counselors can facilitate communication between the patient and the workplace. Therapies should attempt to simulate workplace tasks. A gradual return to work can ease the transition [20].

Procedures

Procedures are discussed in the preceding sections.

Surgery

There is little that can be done surgically to manage postconcussion disorders.

Potential Disease Complications

Persistence of postconcussion symptoms beyond a few months is a possible outcome. Individuals who sustain a second concussion while still symptomatic from a recent concussion may be susceptible to cerebral edema and dangerous increases in intracranial pressure ("second impact syndrome") [77], although some have questioned the existence of such a syndrome [78]. Multiple concussions, even after apparent clinical recovery from earlier episodes, can result in cumulative brain injury with permanent cognitive impairment or even dementia, at times with parkinsonian motor features, depression, or aggression in later life. Unique patterns of pathologic findings consistent with chronic traumatic encephalopathy have been found on autopsy in 68 of 85 people who have had multiple concussions who donated their brains. Most were boxers, football and hockey players, or military veterans. Most had developed cognitive impairment, sometimes associated with depression and suicide [79,80]. The incidence of chronic traumatic encephalopathy is unknown. Athletes and their parents (in youth) may want to discontinue involvement in high-risk sports after one or more concussions or may want to avoid such sports altogether. Caution must be exercised by those responsible for returning athletes to play.

Potential Treatment Complications

Those treating the patient with postconcussion symptoms may contribute to the persistence of symptoms either by overemphasizing the role of brain injury in causing

symptoms with another etiology or, conversely, by overemphasizing psychological factors when brain injury and other physiologic variables are prominent [20,23]. There is often a fine line to be walked, and each patient must be approached individually in this regard, although there are few data available to guide the clinician.

Some of the complications related to medications can appear paradoxical. The frequent use of analgesics (nonsteroidal anti-inflammatory drugs, acetaminophen, and narcotics) can cause rebound headaches, as can the too frequent use of ergotamine and the "triptans." Although they are generally well tolerated, psychostimulants and dopaminergic agents can lead to sedation, worsening attention, irritability, or psychosis. There are myriad other complications possible from the use of the medications mentioned.

ICD-9 Codes

707.00 Decubitus ulcer, unspecified site
707.20 Decubitus ulcer, unspecified stage

ICD-10 Code

L89.90 Pressure ulcer of unspecified site,
unspecified stage

Definition

A pressure ulcer is a localized injury to the skin or underlying tissue, usually over a bone prominence, as a result of pressure or pressure in combination with shear [1]. The development of pressure ulcers due to tissue breakdown and cell necrosis is a significant problem for many patients, including the elderly and those with impaired mobility or paralysis. Pressure ulcers are associated with significant morbidity and even mortality; they can cause pain as well as decreased activities of daily living and quality of life [2]. Therefore this is a pertinent issue for many patients in rehabilitation. Furthermore, they are extremely costly; the burden on the U.S. health care system has recently been estimated at \$6 to \$15 billion per year [3].

Tissue breakdown is referred to by many terms, including decubitus ulcers, pressure sores, ischemic sores, and bedsores. The term *pressure ulcer* is the most accurate nomenclature to describe both the cause and nature of chronic, nonhealing wounds due primarily to excessive applied pressure. This term is used throughout the chapter.

The incidence of pressure ulcers among patients in acute care hospitals ranges from 1% to 33%, with prevalence rates of 3% to 69% [4,5]. Higher rates have been associated with increasing age and duration of hospital stay in

the elderly [6]. In those with spinal cord injury, individuals with paraplegia are more likely to be rehospitalized because of pressure ulcers [7]. The prevalence of pressure ulcers on admission to skilled nursing facilities ranges between 10% and 26% [8,9]. A multicenter study of pressure ulcer incidence in spinal cord injury conducted across the U.S. Model Spinal Cord Injury System [10] found a significant trend toward increasing pressure ulcer prevalence more recently; the most recent period covered by this study was 2002. A consideration of the risk factors in pressure ulcer development is of vital importance because they contribute to the formulation of treatment and rehabilitation strategies. There are many factors that can lead to the development of pressure ulcers. These can be generally classified as intrinsic factors, which are related to the clinical and physiologic profile of the individual, and extrinsic factors, which are primarily attributed to the external environment (Table 148.1). These intrinsic and extrinsic factors can overlap. They highlight the complex nature of the development of pressure ulcers and are indicative of the need for a holistic and systematic approach to prevent their formation.

Intrinsic Risk Factors

Intrinsic risk factors in pressure ulcer development are related to the conditions of the individual patient. Decreased muscle activity and paralysis lead to loss of muscle bulk, thus reducing soft tissue coverage over the bone prominences of the pelvic and other anatomic regions. As muscle bulk decreases, regional vascularity diminishes and the proportion of avascular fatty tissue increases. Loss of normal muscle tone leads to abnormal responses to environmental stimuli, such as applied pressure, thus increasing the risk for blood flow to become compromised.

Furthermore, motor paralysis will directly affect a person's ability to respond unconsciously to potential noxious stimuli (e.g., fidgeting while sitting or turning while asleep). Reduced mobility also profoundly alters the individual's ability to consciously perform postural maneuvers necessary to relieve prolonged applied pressure, from weight shifting while sitting to walking. The loss or reduction of mobility may be further complicated by sensory impairment, leading to the absence or alteration of normal perception of environmental stimuli, such as pain or temperature. Patients with impaired sensation or proprioception are at increased

Table 148.1 Risk Factors in Pressure Ulcer Development

Extrinsic Factors	Intrinsic Factors
Applied pressure Surface shear Local microenvironment	Reduced or absent sensation Impaired mobility Decreased blood flow Muscle atrophy Poor nutrition Systemic diseases (e.g., diabetes) Altered mental status

risk for pressure ulcer development because they cannot sense the warning signals that precede tissue damage.

The malnourished patient is at increased risk for pressure ulcer development and will also have an impaired response to healing. Normal tissue integrity depends on correct nitrogen balance and vitamin intake. Protein depletion will lead to decreased perfusion and impaired immune response. The presence of an exuding pressure ulcer will cause massive protein loss, and the patient will move into increasingly negative nitrogen balance. The severity of a pressure ulcer can be directly related to the degree of hypoalbuminemia [11]. Fluid balance must also be considered in conjunction with nutritional status because dehydration will decrease cellular nutrient delivery.

Patients with systemic diseases may be at higher risk of pressure ulcers. For instance, those with renal disease and diabetes may be more prone to pressure ulcer formation because of their peripheral vascular status. The cognitive and mental status of an individual may also affect the ability to perform pressure relief for at-risk body areas, hence potentially increasing the risk of pressure ulcer formation.

Bowel and bladder incontinence causing excessive local moisture may alter the microenvironment of the skin surface, making it more susceptible to maceration and skin breakdown.

Extrinsic Risk Factors

The primary extrinsic risk factor is external applied pressure. Body tissues can support high levels of hydrostatic pressure, such as in deep sea diving. When pressure is the same in all directions, there is no resulting tissue damage. However, nonuniform applied pressures cause tissue distortion, leading to localized tissue damage. This will occur when a patient is in contact with an external load-supporting device, such as a bed or wheelchair. The pressure at the interface between the patient and the support surface must be maintained at a level such that the local blood supply and lymphatic circulation are not impaired. This threshold varies between individuals, and a specialized support system is often required in high-risk individuals, such as acute spinal cord-injured patients.

Any external load that can cause tissue distortion is also likely to cause shear stresses. When only shear forces are present, slipping occurs, and tissue damage will be minimized. However, shear and normal applied loads generally tend to occur together. The normal applied load required to occlude blood flow can be halved when shear forces are

also present [12]. Significant clinical problems can arise from propping patients up in bed at angles of less than 90 degrees. In contrast, in the side-lying position, it has been found that blood flow is severely impaired by fully lying on the trochanteric region; but at a partial, 30-degree side-lying position, blood flow is maintained [13].

Symptoms

The primary symptoms of a pressure ulcer are due to an area of persistent tissue breakdown involving the skin and underlying tissues. The patients may complain of an open area in the skin, drainage, bleeding, odor, fever, and pain. The severity of pressure ulcers has traditionally been characterized by the extent of breakdown, as described by a staging system.

Physical Examination

Physical examination for a pressure ulcer starts with an overall assessment of the risk factors of the individual and his or her environment. During general examination, evaluation of overall strength, muscle tone, spasticity, range of motion, and presence of contractures is important. Abnormalities in these areas can contribute to both the development and the persistence of pressure ulcers. In addition, it is important to note whether the individual is malnourished, anemic, incontinent of feces or urine, cognitively impaired, or immobile from medical conditions such as stroke or spinal cord injury as well as whether appropriate pressure-relieving surfaces for seating and sleeping have been used. The Braden Scale is a commonly used nursing risk assessment tool to determine whether an individual is at risk for pressure ulcer development [14]. An individual with a score of 18 or lower is found to be at risk. A systematic approach to the examination of the pressure ulcer is necessary to provide accurate assessment and monitoring of the pressure ulcer. The following parameters are to be noted:

- Location of the ulcer
- Size of the pressure ulcer (length to be measured as the maximum measurement craniocaudally; width as the maximum measurement from side to side; depth to be measured at the deepest part of the wound perpendicular to the skin surface)
- Staging of the ulcer
- Presence of undermining or tunneling
- Ulcer bed appearance
- Presence of necrotic materials, slough, eschar, fibrous tissues
- Presence of rolled wound edges
- Presence and amount of drainage (exudate versus transudate)
- Presence of foul odor
- Health of the per ulcer tissues, including any surrounding erythema, maceration, edema, or associated fungal infection

Staging of pressure ulcers describes the extent of tissue breakdown at initial examination. There have been multiple staging systems for pressure ulcers. The National Pressure Ulcer Advisory Panel (NPUAP) and European Pressure Ulcer Advisory Panel (EPUAP) have agreed on the following staging system [1].

Category/Stage I: Non-Blanchable Erythema

Intact skin with non-blanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area. The area may be painful, firm, soft, warmer or cooler as compared to adjacent tissue. Category I may be difficult to detect in individuals with dark skin tones. May indicate “at risk” persons.

Category/Stage II: Partial Thickness

Partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled or serosanguinous filled blister. Presents as a shiny or dry shallow ulcer without slough or bruising (may indicate deep tissue injury). This category should not be used to describe skin tears, tape burns, incontinence associated dermatitis, maceration or excoriation.

Category/Stage III: Full Thickness Skin Loss

Full thickness tissue loss. Subcutaneous fat may be visible but bone, tendon or muscle is *not* exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling. The depth of a Category/Stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput and malleolus do not have (adipose) subcutaneous tissue and Category/Stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep Category/Stage III pressure ulcers. Bone/tendon is not visible or directly palpable.

Category/Stage IV: Full Thickness Tissue Loss

Full thickness tissue loss with exposed bone, tendon or muscle. Slough or eschar may be present. Often includes undermining and tunneling. The depth of a Category/Stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput and malleolus do not have (adipose) subcutaneous tissue and these ulcers can be shallow. Category/Stage IV ulcers can extend into muscle or supporting structures (e.g., fascia, tendon or joint capsule) making osteomyelitis or osteitis likely to occur. Exposed bone/muscle is visible or directly palpable.

In addition, the EPUAP/NPUAP recommends use of the following categories/stages.

Unstageable/Unclassified: Full Thickness Skin or Tissue Loss—Depth Unknown

Full thickness tissue loss in which actual depth of the ulcer is completely obscured by slough (yellow, tan, gray, green or brown) or eschar (tan, brown or black) in the wound bed. Until enough slough and/or eschar are removed to expose the base of the wound, the true depth cannot be determined; but it will be either a Category/Stage III or IV. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as “the body’s natural (biological) cover” and should not be removed.

Suspected Deep Tissue Injury—Depth Unknown

Purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure or *shear*. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared to adjacent tissue. Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment.

This staging system can be used *only* for initial description of the wound. It cannot be used for repeated assessments or reverse staging, primarily because it is not a physiologic description and cannot characterize what is happening in a healing wound. Reepithelialization will occur before lost muscle, subcutaneous fat, or dermis is replaced, resulting in mistakes when healed wounds are staged again.

Care must also be taken in the evaluation of the skin of patients with darkly pigmented skin. Sprigle and colleagues [15] found that erythema in subjects with dark skin is more likely to be nonblanching and to have poor resilience. This indicates that clinicians should use persistence of erythema rather than blanching status to judge incipient pressure ulcers. The staging system defined here includes both visual and nonvisual indicators in the definition of a stage I ulcer, in part to address this issue.

All pressure ulcers are associated with some degree of bacterial colonization, which may or may not lead to local wound infection. The presence of bacterial biofilms in the wound bed may be both a cause and effect of delayed healing [16,17]. Biofilms are typically polymicrobial and are not detected by routine clinical microbiology. They may inhibit healing even in the absence of clinical signs of infection [18]. The possible clinical signs and symptoms of local infection include increasing pain in the wound; erythema, edema, and heat of the periwound area; foul odor; and purulent drainage [19]. Individuals with spinal cord injury may not have intact sensation; in such cases, infected wounds are painless but can cause systemic responses, such as autonomic dysreflexia.

Pressure ulcers also frequently exhibit wound drainage. However, this drainage is not necessarily due to wound infection, and unless it is clinically indicated, routine wound swab culture may not be warranted because this would give a false-positive result. On the other hand, in some cases, increased volumes of exudate may indicate wound infection. Systemic infection may develop if the initial local wound infection is not adequately treated. In such cases, patients may exhibit fever, malaise, and chills. Cellulitis, osteomyelitis, and bacteremia may also develop.

Manual measurement of the wounds by length, width, and depth is the conventional method, but there is poor interrater reliability and the actual surface area of the wound is not known. Electronic technologies allow more accurate documentation and measurements of the surface areas; for instance, the Visitrak device allows easy measurement of wound surface area by a tracing method (Fig. 148.1) [20]. Newer digital stereophotogrammetry systems, such as the LifeViz (Quantificare, San Mateo, Calif) (Fig. 148.2) and Silhouette (ARANZ Medical Ltd, New Zealand) systems, can also provide three-dimensional wound geometry (Fig. 148.3).

Once a pressure ulcer develops, it must be examined regularly for treatment progress to be monitored. At the minimum, weekly assessments should be performed to ensure that the treatment plan is having the desired effect. The NPUAP Pressure Ulcer Scale for Healing (PUSH Tool) has been developed as a clinical tool to monitor changes in pressure ulcer status over time [21]. It takes into account the length and width, exudate amount, and tissue type, forming a composite score that can be tracked

over time. The Bates-Jensen Wound Assessment Tool is a more comprehensive tool that takes into account 12 parameters, including periwound tissue and epithelialization status [22]. These tools have been validated and are used in clinical practice.

Once they are evaluated, it is critically important for pressure ulcers to be clearly documented in medical records. In the United States, accurate identification and documentation of pressure ulcers are required for reimbursement in addition to provision of appropriate patient care. Gunningberg and Ehrenberg [23] found that pressure ulcer prevalence determined by audit of clinical records is less than 50% of the rate found when the patient's skin is examined. Electronic point-of-care wound documentation has the potential to improve wound management with easy-to-use information technology [24]. Dahlstrom and colleagues [25] reported that education on pressure ulcer documentation improved the quality of pressure ulcer documentation by clinical staff. Unfortunately, the same study showed that the implementation of electronic medical records for nursing notes can have a detrimental impact on pressure ulcer documentation in the longer term. This highlights the importance of accurate wound documentation with well-designed templates in the electronic medical record together with ongoing quality improvement.

Functional Limitations

If a pressure ulcer develops, functional limitations are generally exacerbated. For example, the mobility status of a wheelchair user who develops an ischial region pressure ulcer may be affected because treatment can potentially require prolonged periods of total bed rest. Less obvious is a hemiplegic patient who always rolls and pivots to one side to get out of bed; if a greater trochanter pressure ulcer develops on the side that is aggravated by the pressure, shear, and friction of getting out of bed, either that individual will be limited in being able to get out of bed independently or a new technique must be explored.

The development and location of a pressure ulcer may sometimes give an indication of changes in the patient's activity level. For example, an active wheelchair user may develop an ischial region pressure ulcer from sitting for long periods without adequate pressure relief. However, if that same individual presented with a trochanteric pressure ulcer, most likely due to lying in bed for long periods, the clinician would question whether the patient is not getting up and about for physical or mental health reasons that may need further exploration. Changes in body mass should also be evaluated to determine whether the wheelchair and cushion are still appropriate; if a patient gains weight, the wheelchair and cushion can become too narrow, and increased pressures may develop at the greater trochanteric areas because of impingement.

The development of a pressure ulcer will affect many aspects of a patient's daily living activities. Patients in active rehabilitation programs may not be able to participate in therapy; independent mobility and transfers will be restricted, and it may not be possible for appropriate bracing or orthotics to be worn.

Diagnostic Studies

It is well accepted that malnutrition is linked to both the development of pressure ulcers and their ability to heal. A nutritional assessment that indicates malnutrition is a serum albumin level of less than 3.5 g/L, total protein level of less than 6.4 g/dL, or body weight decreased by more than 15% since the prior assessment. Prealbumin has a short half-life of only 2 or 3 days. Prealbumin concentration is an even more sensitive measure than serum albumin level and should be obtained in the determination of acute response to nutritional intervention. A nutritional assessment should be repeated every 12 weeks [10]. It has been proposed that the Mini Nutritional Assessment tool may be a reliable questionnaire-based approach to obtain repeated evaluations in the elderly [26].

Anemia is another important factor that may affect pressure ulcer healing. Therefore, appropriate management of anemia may positively influence the healing of pressure ulcers.

Once a patient has a pressure ulcer, the determination of whether bacterial infection, underlying osteomyelitis, related abscess, or sinus tracts are hindering the healing process becomes important. There are many studies that can help us determine the diagnosis of osteomyelitis. High serum erythrocyte sedimentation rate and C-reactive protein level, although nonspecific, may be an indication of osteomyelitis. Plain radiography of the underlying bone, computed tomography, bone scan, and magnetic resonance imaging can all be used to better assess the underlying and surrounding tissue and bones for possible associated complications. The proper imaging for each patient depends on the history and desired focus of the study. The most definitive and yet most invasive diagnostic study is bone biopsy. This can be done either bedside with a needle or in the interventional radiology suite or the operating room. Culture of the bone biopsy specimen will give the most accurate microbiologic diagnosis of the underlying osteomyelitis, allowing use of the most specific antimicrobial agent for treatment. Routine swab culture of the wounds is not recommended because all wounds are colonized with bacteria; such cultures will only bring about false-positive results, leading to unnecessary and inappropriate antimicrobial treatments.

Matrix metalloproteinases are produced by the wound and inflammatory cells during normal wound healing. However, when they are present in excessive quantities, they have a negative effect on wound healing [27]. Therefore, regulation of excessive matrix metalloproteinases through local treatments such as collagen-based dressings may facilitate healing [28]. Bedside diagnostic testing has been developed to determine protease activity in the wound to facilitate the [29].

Differential Diagnosis

- Ischemic ulcer
- Diabetic ulcer
- Venous stasis ulcer
- Dermatologic neoplasms
- Surgical wound dehiscence
- Abscess
- Abrasion

Treatment

Initial

Unfortunately, pressure ulcers remain one of the most common reasons for readmission to the hospital for many patients with impaired mobility. The patient with a major pressure ulcer will require an average of 180 days of nursing time. Allman and colleagues [30] found that development of a nosocomial pressure ulcer was associated with significant and substantial increases in both hospital costs and length of stay in a group of patients admitted to the hospital with reduced mobility due to a primary diagnosis of hip fracture. Xakellis and Frantz [31] found that the cost of treating pressure ulcers was greatly increased when a patient required hospitalization. Therefore prevention is key to the management of pressure ulcers.

Both the NPUAP/EPUAP [32] and the Consortium for Spinal Cord Medicine [33] have issued comprehensive clinical guidelines for the prevention and treatment of pressure ulcers. Prevention of pressure ulcers aims to address the risk factors listed before. Once a pressure ulcer develops, therapy must focus on local management of the ulcer and systemic treatment of the factors that may affect the healing rate while concurrently addressing factors that led to ulcer formation. Local management of the pressure ulcer should follow the TIME framework for wound bed preparation: *tissue* (nonviable or deficient) management, *inflammation* (and infection control), *moisture* (imbalance), and *edge* (nonadvancing or undermined) [34]. This framework systematically addresses wound bed preparation to optimize healing conditions. Following this framework, nonviable tissue will be debrided. Inflammation or infection will be addressed by appropriate methods, such as the use of an antimicrobial dressing (e.g., silver dressing). Moisture imbalance will be addressed by the retention or removal of fluid by appropriate dressings. Nonadvancing edges will be addressed by the use of débridement, skin grafts, biologic agents, or adjunctive therapies. Figure 148.4 demonstrates the paradigm modified from Sibbald and coworkers [35]; it provides a helpful guideline for chronic wound preparation for treatment.

Wound irrigation with normal saline must be done with adequate pressure to be effective for wound cleaning and mechanical débridement; the pressure of 4 to 15 psi has been found to be safe and nontraumatic to the wound bed. This can be achieved with an appropriate syringe or a pulsatile lavage [36] device that produces irrigation pressure within this recommended range.

With regard to systemic treatments, positioning should be evaluated in both the lying and seated positions. Patients should be positioned to avoid direct pressure and shearing force on the ulcer area (see the section on extrinsic factors). Immobile patients in bed should be turned on a scheduled basis, at least every 2 hours. If necessary, pillows or foam wedges should be used to help patients maintain a position that keeps the ulcer area pressure free. Multiple mattresses and overlays are available, depending on the patient, extent and location of the pressure ulcer, and goals of therapy. For the individuals who can tolerate lying prone, use of a prone cart allows the patient to be out of bed but avoids any pressure on the sacral area. Sitting should be avoided if pressure cannot be relieved from the ulcer area in the sitting position.

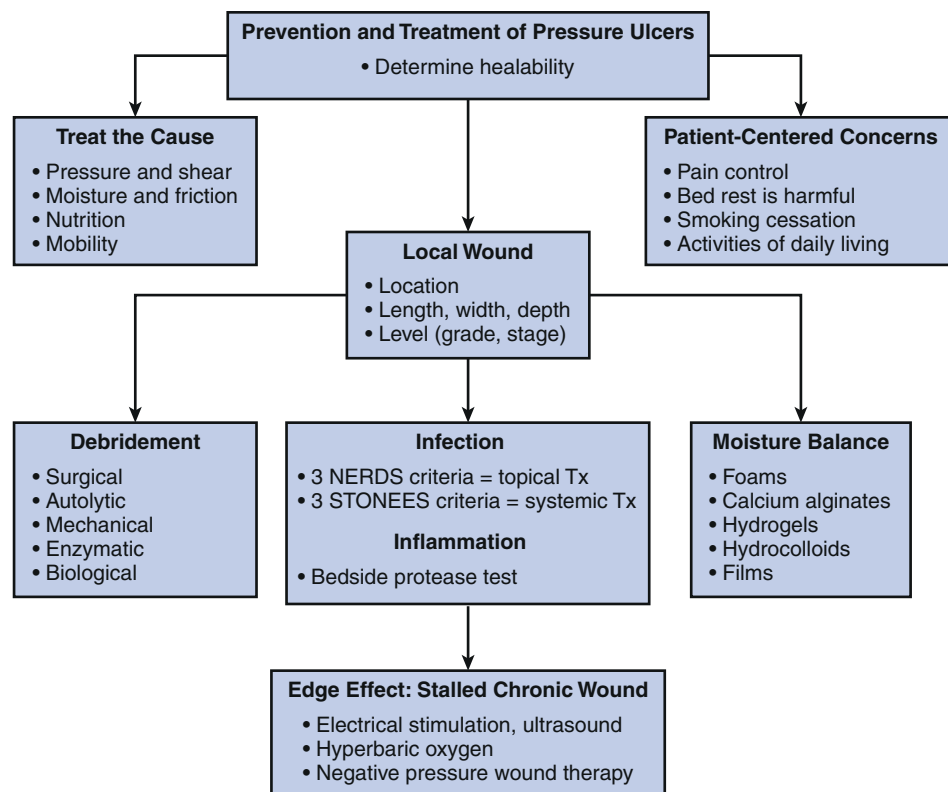

FIGURE 148.4 Wound bed preparation paradigm for holistic patient care. NERDS criteria: nonhealing, exudate increase, red friable or easily bleeding granulation tissue, new slough or debris on the wound surface, and smell. STONEES criteria: size increase, temperature of surrounding skin elevated, os probing or exposed bone, new satellite areas of breakdown, erythema or edema (cellulitis), exudate increase, and smell. Tx, treatment. (From Sibbald RG, Goodman L, Norton L, et al. Prevention and treatment of pressure ulcers. *Skin Therapy Lett* 2012;17:4-7. © Sibbald RG, et al. 2000, 2003, 2006-2007, WHO 2010, 2011-2012.)

The comorbid conditions shown to delay ulcer healing are peripheral vascular disease, diabetes mellitus, immune deficiencies, collagen vascular diseases, malignant neoplasms, psychosis, smoking, and depression. Identification and treatment of these conditions in patients with pressure ulcers are important.

If malnutrition is a factor, aggressive nutritional supplementation or support should be instituted to place the patient into a positive nitrogen balance. Nutritional support should occur if it is likely to change the patient's prognosis. Supplemental arginine, vitamin C, and zinc have been shown to enhance the rate of pressure ulcer healing in patients with low serum albumin and zinc levels and elevated C-reactive protein concentration [37].

Pain should also be addressed and treated appropriately. Some pain may be eliminated or controlled by covering the wound and appropriate positioning. If the pain persists, analgesia is provided as needed during manipulations of the wound and for chronic wound pain.

Within 1 to 2 weeks of the initiation of treatment, partial-thickness pressure ulcers should show signs of healing. Full-thickness ulcers should show reduction in size after 2 to 4 weeks of treatment. This should be determined with some caution; pressure ulcers often appear to be initially larger after treatment because of the effect of débridement and cleaning, exposing the real extent of ulceration. There also appears to be a proportion of pressure ulcers that develop as the result of deep tissue damage, at the interface

between the soft tissues and the bone rather than at the skin surface. These ulcers will often progress to full-thickness ulcers even when appropriate intervention is provided and should be treated more aggressively.

With this in mind, if the ulcer is truly not healing, the different aspects of the treatment plan previously outlined should be reviewed. In addition, biophysical therapies, such as electrical stimulation, ultrasound, hyperbaric oxygenation [38], or negative pressure wound therapy, should be considered together with the possible need for surgical intervention for stage III and stage IV ulcers that are recalcitrant to standard therapy. Electrical stimulation has been shown in multiple studies to improve the rate and degree of healing when it is used in addition to standard interventions on recalcitrant ulcers [32]. Negative pressure wound therapy, such as vacuum-assisted closure, may also be useful for the appropriate wounds. The guidelines for the use of vacuum-assisted closure are as follows [39]:

- There is no untreated, underlying osteomyelitis.
- The wound is free of fistulas to internal organs or body cavities.
- The wound has not decreased in size for 2 to 4 weeks, despite the use of best practices.
- The wound has been sufficiently débrided.
- The wound has not decreased in size by more than 30% 4 weeks after major débridement.

Many different therapeutic modalities for the treatment of pressure ulcers are being investigated, such as growth

factors and tissue-engineered skin substitutes. Basic science research continues to increase our understanding of the chronic wound pathogenesis and can guide the development of clinical interventions. Clinical research in the field of wound treatment is broadening the options for both the treatment and prevention of wounds through many different pathways.

Rehabilitation

Many of the major factors that increase susceptibility to pressure ulcer development are interrelated intrinsic changes in body characteristics and functional abilities. In many conditions, these changes are irreversible. Nutritional status can be altered by adequate diet, but a complete spinal cord injury is permanent. Clinical approaches to pressure ulcer prevention generally focus on extrinsic factors that can be changed. These include educational methods, device-oriented methods, and comprehensive systems of preventive care. These approaches to pressure ulcer prevention are complementary and should be reviewed periodically.

It is critically important during initial rehabilitation that every patient and caregiver be thoroughly educated in the causes of pressure ulcers and what they should do to prevent them. Skills to be learned include the ability to carry out a pressure relief regimen, both through postural changes, when possible, and through the provision of appropriate equipment (e.g., cushions, wheelchairs, mattresses). The need for routine skin inspection and care must also be emphasized, with particular regard to pressure areas such as the ischii, sacrum, greater trochanters, heels, and occiput. Increased care contact time is associated with reduced pressure ulcer incidence, although automated pressure relief systems can also provide an effective intervention during inpatient rehabilitation. Turning every 2 hours while in bed is a commonly accepted practice, but the evidence to support this turning frequency is still lacking. After initial rehabilitation, the at-risk patient must maintain a high level of skin care at all times to prevent the occurrence of pressure ulcers.

The provision of appropriate equipment for postural support and pressure relief, such as mattresses and wheelchair seating cushions, is an important component of rehabilitation. For a patient with impaired mobility who is being discharged to the community or to long-term care, this requires the selection of a wheelchair seating system, including both a wheelchair and a support cushion, to meet his or her individualized requirements. An inappropriate seating system can lead to poor posture, reduce functional abilities, and isolate the user from the environment. All these factors can in turn exacerbate the risk for pressure ulcer development in the rehabilitating patient.

Seating requirements of each patient must be thoroughly assessed during acute rehabilitation and when he or she presents with a pressure ulcer so that appropriate seating and other support surfaces can be recommended. Special seating and cushions are available to help distribute weight off of a pressure ulcer. Cushions can be divided into four categories: foam, viscoelastic foam, gel, and fluid flotation. Which cushion is best for a patient depends on pressure evaluation, lifestyle, postural stability, continence, and cost [40]. Pressure mapping can be a useful component in the

objective determination of the interactions between the seating surface and the skin, helping the clinician to choose the most appropriate seating surface with the best pressure-relieving properties. Pressure relief maneuvers should be done every 15 minutes while the patient is sitting to prevent the development of ischial region pressure ulcers.

Tertiary prevention of pressure ulcers seeks to decrease the number of patients who exhibit chronic recurrence of tissue breakdown. Device-oriented prevention techniques continue to be developed and refined. Active pressure relief mattresses often incorporate temperature sensors to control the microenvironment, and this type of technology is now starting to be applied in wheelchair cushions. Wheelchair cushions that can dynamically alter pressure distribution at the seating interface may provide a method for pressure ulcer prevention in individuals with compromised mobility. Advances in system components have increased the reliability and robustness of these cushions, although they remain relatively expensive. Advanced technologies and new pharmacologic approaches are being explored that can affect the intrinsic clinical status of at-risk patients. The long-term application of implanted electrical stimulation devices offers a unique means to alter the intrinsic characteristics of paralyzed muscle, leading to sustained improvements in regional tissue health [41]. The use of anabolic steroids has also been investigated for both the treatment and prevention of pressure ulcers in the population with spinal cord injury [42].

In addition to altering the intrinsic susceptibility of at-risk patients, the incidence of pressure ulcers may be decreased by ensuring effective delivery of care and education by a multidisciplinary clinical team, at all stages of rehabilitation. A survey of the prevalence of pressure ulcers in 5000 hospitalized patients throughout Europe, carried out by the EPUAP [43], indicated that clinical expertise and standard treatment guidelines are not in themselves sufficient. They should be considered the starting point for effective prevention of pressure ulcers, rather than the endpoint. Personalized interactive programs have the potential to decrease readmission rates for high-risk individuals. An increase in the involvement of the patient in his or her care whenever possible may also decrease susceptibility to pressure ulcer development.

Outpatients at risk for pressure ulcers, such as residents of long-term care facilities, often have restricted ease of community mobility that limits both their desire and ability to access clinical expertise. Telemedicine represents a relatively new model for health care delivery that can eliminate or greatly reduce the need for transportation of the patient and improve standard of care.

Procedures

Débridement of necrotic tissue from the wound is essential for healing to occur. Débridement can be accomplished by several different approaches. Sharp débridement is performed by a qualified clinician who uses a scalpel either at the bedside or in surgery. Mechanical débridement is commonly done with wet to dry dressings changed two or three times a day. Autolytic débridement permits the enzymes in the wound to dissolve the necrotic tissue by covering of the wound with a moisture-retentive dressing. Last, enzymatic débridement uses exogenous enzymes in commercial

preparations, such as papain, to dissolve the necrotic tissue. The determination of débridement method depends on the condition of the wound. Sharp débridement is often performed when there is a large amount of necrotic material; for instance, the presence of eschar tissue often leads to sharp débridement. This will allow efficient removal of necrotic materials from the wound. However, for chronic wounds that do not have easily removable necrotic tissues (e.g., adherent, yellow, necrotic tissues at the base of the wound), enzymatic débridement through the use of collagenase may be the method of choice, allowing nontraumatic débridement of the wound.

Surgery

A variety of surgical options are available to close stage III and stage IV pressure ulcers that do not heal by conservative means. Possible surgeries are as follows: direct closure, split- or full-thickness skin grafts, skin flaps, musculocutaneous flaps, and free flaps. The type of surgical repair depends on the location of the ulcer, the primary diagnosis of the patient, the comorbid conditions, and the goals of treatment. The long-term outcomes of surgical intervention are variable [44]. Predictors of surgical success correlate with the compliance of the patient with postoperative bed rest as well as preoperative risk factors for wound healing.

Potential Disease Complications

The following complications are associated with pressure ulcers: bacteremia, osteomyelitis, cellulitis, amyloidosis, endocarditis, heterotopic bone formation, perineal-urethral fistula, pseudoaneurysm, septic arthritis, sinus track or abscess, and squamous cell carcinoma in the ulcer.

Potential Treatment Complications

Failure to heal and recurrence of pressure ulcers are potential treatment complications. The need to maintain pressure relief over the area of the ulcer may lead to the formation of another pressure ulcer in a different location. Asymmetric sitting posture due to unilateral removal of necrotic bone may cause pressure ulcer development.

Prolonged bed rest and reduced activity levels will decondition the patient and may lead to or exacerbate other comorbidities. Increased pain may occur with dressing changes and sharp or mechanical débridement. Surgical complications of infection, bleeding, and wound dehiscence are possible.

- J43.9** Emphysema, unspecified
- J84.112** Idiopathic pulmonary fibrosis

Definition

Pulmonary rehabilitation (PR) is a comprehensive intervention for patients who remain symptomatic with chronic respiratory disease despite standard medical treatment. Chronic diseases of the lung can be manifested in many forms. Chronic obstructive pulmonary disease (COPD) is among the most common, with an estimated prevalence of at least 8% in the United States. Idiopathic pulmonary fibrosis (IPF) is less common, although the incidence increases with older age, with patients typically presenting after the age of 60 years. PR programs are designed to optimize functional status and to reduce symptoms. A multidisciplinary health

care team evaluates each patient's unique needs, with active collaboration among the patient, family members, and health care providers. Treatment programs are then devised and consist of education, physician-prescribed exercise training, nutritional and psychological counseling, and outcomes assessment. Each program includes a spectrum of intervention strategies that address both the primary condition and the secondary impairments and conditions associated with the respiratory disease, such as peripheral muscle dysfunction, anxiety, and depression. The American Thoracic Society and the European Respiratory Society, in a joint consensus statement, have endorsed the use of PR in the management of chronic respiratory disease regardless of cause [1]. Each prescription is individually specific for PR candidates with the conditions listed in [Table 149.1](#) who have limited exercise tolerance despite standard medical treatment. This includes frequently hospitalized patients and patients undergoing lung volume reduction surgery or lung transplantation, who require PR both before and after surgery.

Symptoms

Symptoms of patients with chronic respiratory diseases such as COPD, due to persistent airflow limitation, and IPF, a condition associated with progressive scarring of the lungs ([Fig. 149.1](#)), include dyspnea, exercise intolerance, cough, and airway congestion. Initially, symptoms may be attributed to other conditions or age itself [2,3]. Whereas COPD patients are relieved by expectorating sputum, IPF patients typically are not. Both COPD and IPF patients may also have chest pain, orthopnea, sleep disordered breathing, poor endurance, anxiety, depression, and difficulty with concentration [3–5]. Inhalation of cigarette smoke is a risk factor for both conditions [3,6]. Disease progression is variable. Fatigue and any complicating conditions can further exacerbate restrictions in activities of daily living (ADLs) and quality of life [7,8]. Late-stage chronic lung disease patients tend to be home bound.

Table 149.1 Conditions Associated with Inadequate Oxygen Supply

Airway Disease	Interstitial Lung Disease*
COPD, emphysema	Idiopathic
COPD, chronic bronchitis	Environmental
Chronic asthma	Occupational
Cystic fibrosis	Granulomatous diseases
Bronchiectasis [†]	Collagen vascular diseases
Constrictive bronchiolitis	Drug-induced, radiation
Hypersensitivity pneumonitis [†]	Inherited

*Interstitial diseases are categorized by causes.

[†]Presents with mixed obstruction and restriction.
COPD, chronic obstructive pulmonary disease.

FIGURE 149.1 High-resolution computed tomography scan of the chest of an individual with idiopathic pulmonary fibrosis. Note subpleural fibrosis (solid arrow) and honeycombing (open arrow).

Physical Examination

Abnormal physical findings are not usually detected early on. Auscultation in COPD may eventually reveal wheezing, hyperresonant lung sounds, prolonged expiratory phase, and rales. Chest percussion may reveal hyperresonance and hyperinflation. The chest may be barrel shaped, which is consistent with hyperinflation. Auxiliary respiratory muscle use and pursed-lip breathing are common with end-stage disease.

The most common finding in patients with IPF is inspiratory “Velcro-like” crackles heard on lung auscultation, mostly in the lower lung fields. Clubbing is found in up to 50% of patients. In advanced IPF, a loud pulmonic second heart sound and peripheral edema may be found, consistent with pulmonary hypertension or right-sided heart failure. Associated signs of arthritis and proximal muscle weakness are uncommon and may suggest interstitial lung disease occurring secondary to a collagen vascular disease.

Functional Limitations

Exercise tolerance and the ability to perform ADLs may be diminished by respiratory and skeletal muscle impairment including all limbs and the trunk [9–11]. Aerobic capacity is typically reduced with early lactate accumulation and

muscle fatigue [9]. With diminished muscle strength, diminished mobility, and ADL restriction, patients become further deconditioned and dependent on others, leading to decreased social interaction, increased anxiety and depression, and being home bound [3,8]. In one study, 41% of COPD patients left the house less than once per month or never in their last year of life [12]. A cycle of diminished mobility leads to further deconditioning and, in turn, worsening exertional tolerance.

Diagnostic Studies

COPD and IPF are suspected for anyone with dyspnea, cough, or exercise intolerance. For IPF, a complete medical history with appropriate serologic tests is warranted to exclude secondary causes of pulmonary fibrosis.

Spirometry is most valuable for diagnosis of COPD and IPF. Spirometry provides quantifiable and reproducible parameters of airflow obstruction and lung restriction. The Global Initiative for Chronic Obstructive Lung Disease has established that a postbronchodilator forced expiratory volume in 1 second (FEV_1) to forced vital capacity (FVC) ratio (FEV_1/FVC) of less than 70% is required for the diagnosis of COPD to be made [3]. COPD severity is stratified by symptoms, postbronchodilator FEV_1 values, and frequency of exacerbations [3]. COPD patients demonstrate an increased total lung capacity, which is consistent with hyperinflation, and an increased residual volume/total lung capacity ratio, which suggests air trapping. IPF patients, in contrast, exhibit severe restrictive physiology with reduced FEV_1 and FVC but a normal or increased FEV_1/FVC ratio and reduced total lung capacity.

Patients with emphysema or IPF have decreased lung diffusion capacity for carbon monoxide consistent with loss of effective gas exchange. Oxyhemoglobin saturation and arterial blood gas values are usually normal at rest until the later disease stages. With exercise, hypoxemia and oxygen desaturation commonly occur.

Chest radiography in patients with advanced COPD commonly reveals evidence of hyperinflation. Other findings may include bullae and increased basilar lung markings. Computed tomography (CT) scan of the chest is not routinely used to diagnose COPD but may show evidence of emphysema and/or bullae.

Bilateral, symmetric reticular opacities, with lower lung field predominance, are usually seen in IPF. High-resolution CT (HRCT) scanning can demonstrate a reticular abnormality with a subpleural, basal predominance; honeycombing with or without bronchiectasis; and absence of findings suggestive of an alternative diagnosis, such as ground-glass opacities, nodules, or cysts [6]. When a patient presents with progressive dyspnea and dry cough without known cause and is found on HRCT to show these “typical” findings, surgical biopsy is not necessary to make the diagnosis. In most other cases, histopathologic correlation is warranted along with pulmonary function testing.

Other diagnostic studies can include testing for α_1 -antitrypsin deficiency for COPD, especially if there is a family history of it. Pulse oximetry allows demonstration of worsening oxygenation with activity. Reduced oxyhemoglobin saturation is an indication for supplemental oxygen therapy. Last, echocardiography is performed when right-sided heart failure is suspected.

Differential Diagnosis

SHORTNESS OF BREATH

Lung disease
Heart disease
Neuromuscular disease
Anemia
Obesity
Deconditioning

Treatment

Management of COPD and IPF includes a comprehensive evaluation for contributing conditions as well as pharmacologic and nonpharmacologic approaches and rehabilitation as noted in Table 149.2. Pharmacologic treatment for COPD is considered in Table 149.3; it is used to reduce dyspnea and frequency of exacerbations and to improve health-related quality of life. For treatment of COPD, short-acting β -agonists and short-acting anticholinergics are equipotent in reducing dyspnea and improving exertional tolerance. In patients with more advanced disease, long-acting bronchodilators are indicated in addition to short-acting bronchodilators [3]. Inhaled corticosteroids are indicated for severe disease or repeated exacerbations despite use of long-acting bronchodilators [3]. Systemic steroids should not be prescribed for stable COPD patients because of an unfavorable risk-benefit ratio. There is insufficient evidence to support the use of any specific pharmacologic therapy for IPF [6].

Nonpharmacologic treatments include airway secretion mobilization, vaccinations (influenza and pneumococcal pneumonia), and education on smoking cessation interventions and the importance of medical regimen adherence and inhaler use techniques. Smoking cessation reduces chronic phlegm production and decreases the rate of loss of FEV₁

compared with continued smokers. Training for proper administration of nebulizers and inhalers promotes optimal medication deposition and efficacy. Thick respiratory secretions can augment dyspnea. N-Acetylcysteine is the only mucolytic readily available in clinical practice in the United States, but there is inconclusive evidence for its efficacy [13].

Patients with advanced COPD have a prevalence of osteoporosis of 36% to 60% and should be treated for osteoporosis [3]. Vertebral fractures have been found in 29% of patients [14]. Immobility as well as smoking, vitamin D deficiency, and the use of glucocorticoids can contribute to osteoporosis.

Long-term oxygen therapy is indicated for COPD patients with hypoxemia, demonstrated by arterial blood gas analysis ($PO_2 < 55$ mm Hg) or by pulse oximetry (oxygen saturation $< 88\%$). Long-term oxygen therapy has been shown to increase endurance and to improve survival [15] as well as to improve sleep and cognitive performance [16]. Data for the use of long-term oxygen therapy in patients with IPF are lacking. Extrapolating from data of COPD patients, supplemental oxygen is recommended for clinically significant resting hypoxemia ($SpO_2 < 88\%$).

Rehabilitation

Goals and Objectives

The goals of a PR program are to reverse deconditioning and to optimize the individual's independence and functioning. A PR service aims to alleviate symptoms, to increase physical and social participation, to maximize independent functioning, and to enhance quality of life, all in the framework of reducing health care costs [1]. Specific objectives to improve exercise tolerance, strength, and flexibility as well as coping strategies and stress management require periodic reassessment. Patients, their families, and a multidisciplinary PR team work together to achieve the objectives.

Staffing

Specific PR team staffing varies and depends on resources and availability. All programs have a physician medical director who is responsible for initial patient assessment to determine candidacy for PR, to identify comorbidities, and to ensure an optimal medical regimen [17]. The physician must be accessible for emergencies when inpatient or outpatient services are being furnished.

A well-structured PR team also consists of therapists (physical, occupational, respiratory), a nutritionist, an exercise physiologist, and a social worker [18]. A psychiatrist or psychologist may also be part of the team. The main role of the physical or respiratory therapist is to carry out the prescribed exercise program (Table 149.4), whereas the occupational therapist evaluates the patient's environment and ADLs and makes recommendations for adaptive equipment to optimize ADLs. The respiratory therapist also teaches breathing exercises as well as proper use of aerosolized medications and oxygen. An exercise physiologist prescribes and monitors the therapeutic exercise program. The nutritionist formulates the nutritional goals and educates on proper diet. The social worker assesses any need for home services and counsels and instructs in coping strategies, especially if a psychiatrist or psychologist is not part of the team. All members' assessments are integrated into specific treatment plans.

Alternative breathing techniques
Energy conservation techniques
Therapeutic modalities
Adaptive devices and mobility equipment
Psychosocial counseling
Nutritional counseling
Patient and caregiver education
Maintenance program

Table 149.3 Commonly Prescribed Medications for Chronic Obstructive Pulmonary Disease

Drug Class	Commonly Prescribed Formulations	Modes of Delivery	Effect and Indication
Short-acting β_2 -agonist	Albuterol	Inhaler, nebulizer solution, pill	Bronchodilator; used as needed for symptom relief
Short-acting anticholinergic	Ipratropium bromide	Inhaler, nebulizer solution	Bronchodilator; used as needed for symptom relief
Long-acting β_2 -agonist	Salmeterol Formoterol	Inhaler, nebulizer solution	Bronchodilator; used daily for maintenance
Long-acting anticholinergic	Tiotropium bromide Aclidinium bromide	Inhaler	Bronchodilator; used daily for maintenance
Inhaled corticosteroid	Beclomethasone Budesonide Fluticasone	Inhaler, nebulizer solution	Anti-inflammatory; used daily for maintenance
Methylxanthine derivative	Theophylline	Pill	Bronchodilator (less effective than inhaled bronchodilators); used daily for maintenance
Phosphodiesterase type 4 inhibitors	Roflumilast	Pill	Anti-inflammatory (nonsteroid); used daily for maintenance (in patients with chronic bronchitis)

Combination inhalers are available in different formulations: short-acting β_2 -agonist and short-acting anticholinergic; long acting β_2 -agonist and inhaled corticosteroid.

Table 149.4 Types of Exercise [1,2,8,12,13,24,25]

Type of Exercise	Example
Ventilatory muscle training	Inspiratory resistive exercise: maximum sustained ventilation, inspiratory resistive loading, inspiratory threshold loading, sustained hyperpnea
Strength training	Upper extremity exercise: pulleys, elastic bands, supervised circuit training, weightlifting with low resistance Lower extremity exercise: supervised circuit training, weightlifting with low resistance
Endurance training	Upper extremity exercise: unsupported upper extremity activities ranging from activities of daily living to athletic activities, supervised arm cycling, low-impact aerobics, pool therapy Lower extremity exercise: incremental treadmill program, supervised walking, cycling and stair climbing program, low-impact aerobics, pool therapy

Setting

Most PR programs are carried out in the outpatient setting, although inpatient and home settings are also possibilities. Inpatient- and outpatient-based programs facilitate interaction with a more complete PR team in a safe environment. Inpatient PR is usually reserved for patients with severe impairments and multiple comorbidities or for difficult-to-transport severely disabled patients. Home-based rehabilitation is more convenient for the severely disabled, but team interaction is limited. PR is beneficial irrespective of setting [1,18–20]. Indeed, home-based PR can be of equivalent benefit to hospital-based programs [20]. Telemonitoring may now allow a hybrid of home- and hospital-based monitoring as well as enhanced

clinical data collection and more prompt interventions from the PR team. Domiciliary telemonitoring and home-based PR may decrease hospitalizations for respiratory complications [21]. Whereas efficacy of PR for patients with IPF is limited, it seems that many would benefit. Swigris [22] reported an improved sense of well-being, a greater sense of control, more energy, and a better general outlook on life. Outpatient PR programs also resulted in improvements in 6-minute walk distance and health-related quality of life for IPF patients, although pulmonary function and oxygenation did not improve [23–25]. Home-based programs may be equally effective [26]. Larger controlled studies are needed.

Rehabilitation Treatment Modalities

Because there are insufficient resources to provide PR to all symptomatic patients, attention to the following increases the likelihood of success: the patient's respiratory condition should be stable on prescribed medical therapy including supplemental oxygen, with demonstrated adherence to the medical regimen before enrollment in PR; underlying medical conditions (e.g., cardiac disease or psychiatric illness) should be stable; and no medical conditions or physical impairments should be present that would interfere with the PR process [1]. The patient also needs to be able to understand the educational content of the program and be motivated and willing to devote the necessary time. PR dropout rates are highest among current smokers [27,28].

Although cigarette smoking is sometimes considered a contraindication to PR, clinical and physiologic gains can be similar in smokers and nonsmokers [27–29]. A trial of smoking cessation can be offered as an index of the patient's motivation for PR [29].

Morbidity due to trapping of airway secretions may be relieved by the many secretion mobilization systems now available, but there is no clear evidence that one system works better than any other. The least expensive and simplest methods to supplement airway secretion mobilization efforts, such as use of a flutter valve, positive expiratory

pressure mask, and chest vibrators, are probably as effective as the expensive chest vibrating and oscillating devices [30]. Supplemental respiratory therapeutic secretion mobilization methods that can be taught include chest percussion and postural drainage, huffing, and active cycle of breathing. The last is the most inexpensive technique of airway secretion mobilization because no assistive device is used. The patient simply breathes slowly and shallowly at lung volumes well below functional residual capacity. He or she gradually increases tidal volumes to approach functional residual capacity and, once reaching it, takes a deep breath and “huffs” out secretions. Other important strategies for these patients are to administer and to monitor compliance with medications.

Carefully prescribed maximally intense anaerobic exercise over 30- to 45-minute periods provides the greatest benefits for reducing dyspnea and respiratory rate and increasing exercise tolerance, maximum oxygen consumption, 6- and 12-minute walk distance, ADLs, work output, mechanical efficiency, and possibly gas exchange while decreasing anxiety and depression [31–35].

For advanced patients who cannot tolerate high-intensity training, low-intensity training can be prescribed on the basis of objective or subjective measures. Objective measures involve calculating or measuring the maximal oxygen consumption or maximum heart rate. If open-circuit spirometry and metabolic cart are available, specific target intensity may be 50% of peak rate of oxygen uptake. Heart rate parameters may be most useful for patients with cardiac conditions. Several formulas are used. One is the desired exercise intensity multiplied by the maximum predicted heart rate. Hence, if the desired exercise intensity is defined as 60% of maximum predicted heart rate (HR), then

$$\text{Target HR} = 0.60 \times [\text{HR}_{\text{max}} = 220 - \text{age}]$$

Another is the Karvonen formula. For the target HR range of 50% to 85%:

$$\begin{aligned} \text{HR reserve} &= [(\text{HR}_{\text{max}} - \text{HR}_{\text{rest}}) \times 0.50] + \text{HR}_{\text{rest}} \\ &= [(\text{HR}_{\text{max}} - \text{HR}_{\text{rest}}) \times 0.85] + \text{HR}_{\text{rest}} \end{aligned}$$

Initial targets can be 50% (range, 50% to 80%) of either objective measure or the level tolerated by the patient [36].

When objective measures are not applicable, as in the case of patients taking negative chronotropic medications (e.g., beta blockers or calcium channel blockers) and heart transplant patients, subjective measures may be more predictive of exercise tolerance. In addition, because patients are often limited by exertional dyspnea, subjective measures may be more desirable [36].

Subjective measures of exercise tolerance, such as the Borg Rating of Perceived Exertion Scale or dyspnea rating scale, provide patient feedback based on symptoms alone. The Borg Rating of Perceived Exertion Scale from 6 to 20 is linearly related to heart rate. This is illustrated by multiplying the chosen scale number by 10 to obtain the estimated predicted heart rate. For example, when the patient chooses the number 10 on the scale to describe exertion symptoms, heart rate is estimated by the following equation:

$$10 \times 10 = 100 (\pm 10)$$

The original Borg scale uses this method [36,37].

Daily activities in mobility and exercise are tailored to the patient's form of mobility and baseline level of function. Mobility and endurance exercise programs can include walking, stair climbing, low-impact aerobics, stationary bicycling, and pool activities. For mobility, work, and recreational pursuits, assistive devices to improve ADLs can include wheelchair, walker, or cane. Strength training increases ADLs, mobility, and specific occupation-related tasks. Intermingled with endurance, strength, and task-specific training are energy conservation techniques that provide the patient with more energy efficient methods to perform daily activities. Increased endurance for exercise can occur independently of changes in ventilatory muscle endurance. The patient is made responsible for a progressive program to reinforce adherence and independence.

Breathing retraining goals modify the breathing pattern to decrease the work of breathing and to improve cough. Pursed-lip breathing and diaphragmatic breathing decrease the respiratory rate, coordinate the breathing pattern, and tend to prevent collapse of smaller bronchi. Air shifting is performed several times per hour. It involves a deep inspiration that is held with the glottis closed for 5 seconds. The air shifts to lesser ventilated areas of the lung and may help prevent microatelectasis. The subsequent expiration is through pursed lips. Pursed-lip breathing aids in relaxation as well. Other relaxation exercises, such as Jacobson exercises and biofeedback, can be used to decrease tension and anxiety [38,39].

For hypercapnic patients, interspersing periods of respiratory muscle rest with exercise of specific respiratory muscle groups is a principle of PR. Rest can be achieved by overnight use of nasal bilevel positive airway pressure, which improves daytime gas values, increases vital capacity, decreases fatigue, and increases well-being and quality of life [40,41].

After the acute rehabilitation period, continued surveillance and attention to abstinence from smoking, bronchial hygiene (Table 149.5), breathing retraining, physical reconditioning, oxygen therapy, and airway secretion mobilization have been shown to reduce hospital admissions, length of hospital stays, and cost [42,43]. The benefits of PR therapeutic exercise on exercise performance and quality of life are greatest during the first year and last up to 5 years [44–46].

Table 149.5 Pulmonary Hygiene Options
[11,14,43]

Inhaled Treatments

Bronchodilators
Mucolytics

Methods of Airway Secretion Elimination

Oral, nasal, or transtracheal suctioning
Chest percussion and postural drainage
Positive expiratory pressure breathing
Flutter mucus clearance devices
Mechanical vibration devices to the chest wall
Intrapulmonary percussive ventilation with aerosolized medications
Mechanical insufflation-exsufflation applications
Autogenic drainage
Manual assisted cough
Abdominal binder

So far, there is not enough evidence to support improved survival with PR. As reported by Troosters and colleagues [47], in a pooled analysis of some small studies, 1-year to 18-month mortality risk was 7.8% in the PR group and 9.9% in the control group. The pooled odds of dying in the PR group was 0.69 compared with the control group. This suggests that PR reduces the short-term risk of dying by 31%, although this was not statistically significant. In 2011, a Cochrane review concluded that PR after an acute exacerbation of COPD was safe and associated with a reduction in mortality [48].

Surgery

Lung volume reduction surgery is an option for patients with predominantly upper lobe emphysema and low baseline exercise capacity. Results from the National Emphysema Treatment Trial demonstrated that lung volume reduction surgery in this subset of patients improved exercise capacity and quality of life and reduced mortality compared with a similar group of patients treated medically and that this benefit was maintained on a 5-year follow-up assessment [49]. Lung volume reduction surgery is contraindicated in patients with low FEV₁, homogeneous emphysema, or very low carbon monoxide diffusing capacity because of the increased risk of death after surgery [50]. More recently, lung volume reduction by bronchoscopic techniques has been introduced, and studies of the effectiveness of this approach are ongoing.

Lung transplantation is an option for selected patients with COPD or IPF. Appropriate patients for lung transplantation have severe disease as defined by a low FEV₁% predicted (<25%), resting hypoxemia, hypercapnia, and secondary pulmonary hypertension. Referral for lung transplantation should be considered for COPD patients with progressive deterioration despite optimal treatment. After lung transplantation, quality of life and functional capacity have been demonstrated to improve [51]. Appropriate IPF patients for transplantation have a lung diffusion capacity for carbon monoxide of less than 39% of predicted, a decrement in FVC of more than 10% during 6 months of follow-up, a decrease in oxygen saturation below 88% during a 6-minute walk test, and honeycombing on HRCT. Five-year survival rates after lung transplantation in IPF are about 50%, with improvement demonstrated in oxygenation and spirometry, lung volumes, and diffusing capacity [52].

Potential Treatment Complications

Treatment complications can result from oxygen toxicity, barotrauma from ventilator use, and patient comorbidities such as concomitant cardiac or atherosclerotic peripheral vascular disease and pharmacologic treatment. Routine evaluation of a patient's medication profile by the treating clinician is necessary. Immobility due to muscle weakness or acute illness can also exacerbate pulmonary secretion stasis and cause deep venous thromboses, cardiac deconditioning, skin ulceration, and bone decalcification. Each individual's progress with mobilization, exercise, and daily activity facilitation programs is monitored, and prescriptions are modified accordingly.

E0461 Noninvasive mechanical ventilation
E0450 Invasive mechanical ventilation
335.20 Amyotrophic lateral sclerosis
359.9 Myopathy disorders
V46.11 Dependence on ventilator

ICD-10 Codes

G12.21 Amyotrophic lateral sclerosis
G72.89 Myopathy

Definition

Neuromuscular disorders such as amyotrophic lateral sclerosis and myopathic disorders most often result in respiratory morbidity and mortality caused by weakness of the respiratory muscles. The three respiratory muscle groups are the inspiratory muscles, the expiratory (predominantly abdominal and upper chest wall) muscles for coughing, and the bulbar-innervated muscles. Whereas the inspiratory and expiratory muscles can be completely supported by physical aids such as continuous noninvasive ventilation (NIV), as presented here, and some patients have used this for more than 50 years without resort to tracheostomy (Fig. 150.1), there are no effective noninvasive measures to assist bulbar-innervated muscle function [1,2].

Symptoms

Patients with diminished ventilatory reserve who are able to walk complain of exertional dyspnea; but wheelchair users'

symptoms may be minimal except during intercurrent respiratory infections, when they complain of anxiety, inability to fall asleep, and possibly dyspnea. Morning headaches, fatigue, sleep disturbances, and hypersomnolence result from nocturnal hypoventilation or the decreased ability to recruit accessory respiratory muscles during sleep [3].

Physical Examination

Signs of inspiratory muscle impairment and hypoventilation can include tachypnea, paradoxical breathing, hypophonia, nasal flaring, accessory respiratory muscle use, cyanosis, flushing or pallor, anxiety, and airway secretion congestion. Lethargy, obtundation, and confusion signal carbon dioxide (CO₂) narcosis. Often there are no signs at all despite symptoms of hypoventilation. The rest of the physical examination is usually typical for neuromuscular disorders (see, for example, Chapters 132 and 135).

Functional Limitations

With diminished respiratory reserve, walking becomes limited by dyspnea in going up stairs or walking long distances. Once a patient is wheelchair dependent and incapable of independently performing few activities of daily living, there are no additional functional limitations associated with chronic hypoventilation. However, symptoms of hypoventilation and CO₂ levels may increase until patients become obtunded or develop CO₂ narcosis.

Diagnostic Studies

Respiratory muscle dysfunction and hypoventilation are diagnosed by end-tidal CO₂ monitoring (capnography), oximetry, spirometry, and assessment of cough peak flows. The end-tidal CO₂ is 2 to 6 mm Hg less than arterial Pco₂. The vital capacity (VC) is measured in sitting and supine positions and should not be significantly different in either position. Because hypoventilation is worse during sleep, the supine VC is more important. Orthopnea is common when the VC is less than 25% of normal or the VC in the supine position is at least 20% less than in the sitting position. The normal difference in VC between sitting and the supine position is less than 7%. Patients wearing thoracolumbar

FIGURE 150.1 A 68-year-old woman who has depended on noninvasive mechanical ventilation around-the-clock since 1954 and used mouthpiece noninvasive intermittent positive pressure ventilation with the mouthpiece fixed adjacent to the sip and puff motorized wheelchair controls for daytime support since 1957.

bracing should have the VC measured both with the brace on and with it off because a brace that fits well can increase VC, whereas one that restricts respiratory muscle movement can decrease it.

Patients are taught glossopharyngeal breathing (GPB), and its progress is measured spirometrically, as is air stacking. Air stacking and GPB are used for lung volume recruitment. Patients air stack by receiving consecutively delivered volumes of air through a manual resuscitator or volume-cycled ventilator that are held by the glottis to the greatest volume possible. The maximum volume that can be held by the glottis, the maximum insufflation capacity (MIC), is determined spirometrically. Likewise, GPB can often provide volumes of air to or beyond those achieved by air stacking and is also measured spirometrically [4]. A nasal interface or oral-nasal interface can be used for air stacking when the lips are too weak for effective air stacking through the mouth (Fig. 150.2).

Cough peak flows are measured with a peak flow meter (Access Peak Flow Meter; Healthscan Products Inc, Cedar Grove, NJ). Cough peak flows of 160 L/min are minimal and often ineffective [4]. The attainment of (unassisted) cough peak flows above 160 L/min is the best indicator for successful tracheostomy tube removal irrespective of remaining pulmonary function [4]. Patients with VCs of less than 1500 mL have assisted cough peak flows measured from a maximally air stacked volume of air with an abdominal thrust delivered simultaneously with glottic opening [5]. A cough produced from a deep air stacked volume and with an abdominal thrust applied concomitantly with glottis opening is a “manually assisted cough”; its efficacy is also determined by peak flow meter.

For the stable patient without intrinsic pulmonary disease, arterial blood gas sampling is unnecessary. Besides the discomfort, 25% of patients hyperventilate as a result of anxiety or pain during the procedure [6].

For symptomatic patients with normal VC, an unclear pattern of oxyhemoglobin desaturation, and no apparent hypercapnia, polysomnography is warranted [7]. Polysomnography is unnecessary for symptomatic patients with decreased VC because it is programmed to interpret every apnea and

FIGURE 150.2 A 36-year-old man with Duchenne muscular dystrophy using nasal prongs interface for air stacking and for daytime ventilatory support.

hypopnea as resulting from central or obstructive events rather than from inspiratory muscle weakness.

Whereas all clearly symptomatic patients with diminished lung volumes require a trial of NIV to ease symptoms, if symptoms are questionable, nocturnal continuous capnography and oximetry are useful and most practically done in the home. A questionably symptomatic patient with decreased VC, multiple nocturnal oxyhemoglobin desaturations below 95%, and elevated nocturnal CO₂ should be encouraged to undergo a trial of nocturnal NIV.

Treatment

Initial and Habilitation

Lung Volume Recruitment

The initial intervention goals are to promote normal lung and chest wall growth for children; to maintain lung and chest wall compliance, lung growth, and chest wall mobility; and to increase cough peak flows to prevent intercurrent respiratory tract infections from developing into pneumonias and respiratory failure.

Pulmonary compliance is diminished and chest wall contractures and lung restriction occur when the lungs cannot be expanded to predicted inspiratory capacity. As the VC decreases, the largest breath one can take expands only a fraction of lung volume. Like limb articulations, regular mobilization is required. This can be achieved only by providing deep insufflations, air stacking, or nocturnal NIV [8]. The primary objectives of lung expansion therapy are to increase VC and voice volume, to maximize cough peak flows (Fig. 150.3), to maintain pulmonary compliance, to diminish atelectasis, and to master NIV because anyone who can air stack through a mouthpiece can use mouthpiece NIV and therefore be successfully extubated and decannulated even if not ventilator weaned (Table 150.1).

Bulbar muscle function and glottis function are objectively quantitated by the extent to which the MIC exceeds VC (MIC – VC). Thus, one who cannot air stack cannot close the glottis and must be passively insufflated by a pressure-cycled ventilator or CoughAssist (Respironics International Inc, Murrysville, Pa) at pressures of 40 to 70 cm H₂O or by a manual resuscitator with the exhalation

FIGURE 150.3 Graph over time of vital capacity, maximum insufflation capacity, and glossopharyngeal maximum single-breath capacity of a 47-year-old continuous mouthpiece/nasal intermittent positive pressure ventilation user with Duchenne muscular dystrophy. GPB, glossopharyngeal breathing; MIC, maximum insufflation capacity. (From Bach JR, DeCicco A. Forty-eight years with Duchenne muscular dystrophy. *Am J Phys Med Rehabil* 2011;90:868-870.)

Table 150.1 Extubation Criteria for “Unweanable” Ventilator Users

- Oxyhemoglobin saturation (SpO_2) $\geq 95\%$ in ambient air
- $\text{Paco}_2 \leq 40$ mm Hg at peak inspiratory pressures < 30 cm H_2O on ventilatory support up to full settings
- Afebrile and normal white blood cell count
- Any acute oxyhemoglobin desaturations below 95% reversed by mechanically assisted coughing
- Fully alert and cooperative, receiving no sedative medications
- Air leakage through upper airway sufficient for vocalization on cuff deflation
- Chest radiograph abnormalities cleared or clearing

valve blocked. The maximum passive insufflation volume has been termed the lung insufflation capacity [8]. In 282 evaluations of VC, MIC, and lung insufflation capacity, the mean values were 1131 ± 744 mL, 1712 ± 926 mL, and 2069 ± 867 mL, respectively [9].

Cough Flow Augmentation

Manually assisted coughing involves air stacking to a deep lung volume for any patient with less than 1500 mL of VC, then applying an abdominal thrust timed to glottic opening. For 364 patients able to air stack, whereas the mean VC was 997 mL, the mean MIC was 1648 mL, and although cough peak flows were 135 L/min, mean assisted cough peak flows were 235 L/min. This can be the difference between developing pneumonia and coughing effectively to prevent it [10]. The inability to generate 160 L/min of assisted cough peak flows despite having a VC or MIC greater than 1 L indicates upper airway obstruction, which can be due to severe bulbar muscle dysfunction or other lesion that should be identified by laryngoscopy so that reversible lesions can be corrected.

Mechanically assisted coughing (MAC) is the combination of the use of mechanical insufflation-exsufflation (CoughAssist) with an exsufflation-timed abdominal thrust. Deep insufflations followed immediately by deep exsufflations at pressures of 50 to -50 or greater cm H_2O are usually the most effective and preferred. MAC can be provided by an oral-nasal mask, a simple mouthpiece, or a translaryngeal or tracheostomy tube. When it is delivered by a translaryngeal or tracheostomy tube, the cuff, when present, should be inflated. The CoughAssist can be manually or automatically cycled. Manual cycling facilitates caregiver-patient coordination of inspiration and expiration with insufflation and exsufflation, but it requires hands to deliver an abdominal thrust, to hold the mask on the patient, and to operate machine cycling.

Procedures

Lung Volume Recruitment

Before patients' VCs decrease to 70% of predicted normal, they are instructed to air stack 10 to 15 times two or three times daily, usually with a manual resuscitator. Because of the importance of air stacking, NIV is provided through ventilators using volume rather than pressure cycling.

Infants cannot air stack or cooperate with passive insufflation therapy. All small children with paradoxical breathing require nocturnal NIV to prevent pectus excavatum and to promote lung growth as well as for inspiratory muscle assistance [11]. Deep insufflations can also be timed to the child's breathing and delivered through an oral-nasal interface. Children can become cooperative with deep insufflation therapy by 14 to 30 months of age.

Cough Flow Augmentation

Cough flows are augmented and sputum expelled by delivery of about five cycles of MAC followed by a short

period of normal breathing or ventilator use to avoid hyperventilation until offending sputum is expelled and oxyhemoglobin saturation levels, if diminished, return to 95% or greater. Insufflation and exsufflation times are adjusted to provide maximum observable chest expansion and rapid full lung emptying. In general, 2 to 4 seconds are required. Treatment continues until no more secretions are expelled and secretion-related oxyhemoglobin desaturations are reversed. Use can be required as often as every 30 minutes around-the-clock during chest infections.

The use of mechanical insufflation-exsufflation through the upper airway can be effective for children as young as 11 months, who can occasionally facilitate its efficacy by not crying or closing the glottis. Between 2.5 and 5 years of age, most children cooperate with it. Before that, the insufflations and exsufflations and exsufflation-timed abdominal thrusts are timed to the child's own breathing cycle.

Conventional airway suctioning misses the left main stem bronchus about 90% of the time [12]. However, MAC can provide effective flows in both left and right airways without the discomfort or airway trauma. Patients prefer MAC to suctioning [13]. Deep suctioning, whether by tube or upper airway, can be discontinued for most patients.

VC, pulmonary flow rates, and SpO_2 , when abnormal, can improve immediately with clearing of airway secretions by MAC [14]. An increase in VC of 15% to 42% was noted immediately after treatment in 67 patients with "obstructive dyspnea," and a 55% increase in VC was noted after MAC for patients with neuromuscular disorders [15]. We have observed 15% to 400% (200 to 800 mL) improvements in VC and normalization of SpO_2 for patients during chest infections [16].

Of the three muscle groups required for effective coughing, MAC can take the place of only the inspiratory and expiratory muscles. Thus, ventilator users with intact bulbar muscles can usually air stack to volumes of 3 L or more and, unless very scoliotic or obese, can achieve effective assisted cough peak flows of 6 to 9 L/s and do not need MAC. The patients who need MAC the most have moderately impaired bulbar muscle function that limits assisted cough peak flows to less than 300 L/min. This is typical of Duchenne muscular dystrophy and other myopathies [10]. Patients with respiratory muscle weakness complicated by scoliosis and inability to capture the asymmetric diaphragm by abdominal thrusting can also greatly benefit from MAC (Table 150.2).

Surgery

No surgery is indicated in these patients.

Potential Disease Complications

The great majority of morbidity and mortality for patients with neuromuscular disease is due to complications of respiratory muscle weakness. In particular, these patients develop life-threatening chronic alveolar hypoventilation. Life can be prolonged by ventilatory assistance or support, which is usually administered invasively but can be administered noninvasively by use of physical medicine respiratory muscle aids. Respiratory orthopnea, symptoms of hypoventilation noted before, and paradoxical breathing in children indicate the need for nocturnal noninvasive intermittent positive pressure ventilation (NIV) [11]. Because, in general, only patients improperly treated with supplemental oxygen develop CO_2 narcosis and respiratory failure is generally caused by ineffective cough and airway secretion management, any patient finding that NIV use is more burdensome than his or her symptoms is told that it is all right to discontinue it for now but to return regularly for reevaluation.

Although the inspiratory muscles can be assisted by applying pressures to the body, negative pressure body ventilators cause obstructive apneas, are less effective than NIV, and become even less effective with age and decreasing pulmonary compliance [17]. A useful body ventilator, the intermittent abdominal pressure ventilator (IAPV) or Exsufflation Belt (Respironics International Inc, Murrysville, PA), involves the intermittent inflation of an elastic air sac that is contained in a corset or belt worn beneath the patient's outer clothing. The sac is cyclically inflated by a positive pressure ventilator. This moves the diaphragm upward to assist in expiration. With bladder deflation, gravity causes the abdominal contents and diaphragm to return to the resting position, and inspiration occurs. A trunk angle of 30 degrees or more from the horizontal is required for effectiveness. A patient can add to the IAPV-delivered volume by breathing or GPB along with it. The IAPV augments tidal volumes by 300 mL to as high as 1200 mL and is often preferred to mouthpiece NIV by patients with little autonomous breathing ability during daytime hours [18].

Noninvasive Intermittent Positive Pressure Ventilation

NIV can be delivered by lip seal, nasal, and oral-nasal interfaces during sleep or by a mouthpiece or nasal interface during daytime hours. Mouthpiece and nasal NIV are open systems that require the user to rely on central nervous system reflexes to prevent excessive insufflation leakage during

Table 150.2 Management of Patients with Spinal Cord Injury

Level*	Vital Capacity	Bulbar Function/Neck Function†	Daytime	Nocturnal
Above C1	0	Inadequate/inadequate	TIPPV	TIPPV
C2-C3	<200 mL	Adequate/inadequate	EPP/DP	NIPPV/MIPPV
Below C2	>200 mL	Adequate/adequate	MIPPV/IAPV	NIPPV/MIPPV

*Motor levels.

†Adequate neck function involves sufficient oral and neck muscle control to rotate, flex, and extend the neck to grab and use a mouthpiece for intermittent positive pressure ventilation. Adequate bulbar function prevents aspiration of saliva to the degree that the SpO_2 baseline decreases below 95%.

DP, diaphragm pacing; EPP, electrophrenic pacing; IAPV, intermittent abdominal pressure ventilation; MIPPV, mouthpiece intermittent positive pressure ventilation; NIPPV, nasal intermittent positive pressure ventilation; TIPPV, tracheostomy intermittent positive pressure ventilation.

sleep [3,19]; thus, supplemental oxygen and sedatives can render it ineffective. NIV can be introduced in the clinic or home setting.

There are numerous commercially available nasal interfaces (continuous positive airway pressure masks). Several should be tried and their use alternated to avoid prolonged skin pressure. Excessive insufflation leakage can be avoided, if necessary, by switching from an open to a closed system with use of a lip seal–nasal prongs system. Such interfaces deliver air through the mouth and nose during sleep and require minimal strap pressure. This optimizes skin comfort and minimizes air (insufflation) leakage.

The most useful method for daytime ventilatory support is NIV through a 15-mm angled mouthpiece. Some keep the mouthpiece in the mouth all day, but most have it fixed near the mouth by a metal clamp attached to a wheelchair for this purpose [20–22]. The mouthpiece can also be fixed onto motorized wheelchair controls (e.g., sip and puff, chin, and tongue controls). Large volumes of 800 to 1500 mL are delivered so that the patient can take as much air as desired for each breath to vary tidal volumes, speech volume, and cough flows as well as to air stack. Neck movement and lip function are needed to use mouthpiece NIV; otherwise, a nasal prongs system is used for daytime support [18]. Nasal NIV is also most practical for nocturnal and daytime use by infants. Other than perhaps for uncontrollable seizures and the inability to cooperate, there are no contraindications to the use of NIV long term.

Glossopharyngeal Breathing

Both inspiratory and, indirectly, expiratory muscle function can be assisted by GPB [23]. This is the glottis pistoning boluses of air into the lungs. One GPB breath usually consists of six to nine gulps of 40 to 200 mL each (Fig. 150.3). During the training period, its efficiency can be monitored by spirometrically measuring the milliliters of air per piston action, piston actions per breath, and breaths per minute. A training manual [24] and numerous videos are available [25], the most analytical of which was produced in 1999 [26]. GPB can provide an individual with no VC with ventilator-free breathing tolerance up to all day [23,27].

Severe oropharyngeal muscle weakness can limit or eliminate the usefulness of GPB. However, we have managed 13 Duchenne muscular dystrophy ventilator users who had no breathing tolerance other than by GPB [28]. Approximately 60% of ventilator users with no autonomous ability to breathe but with good bulbar muscle function can use GPB for ventilator-free breathing up to all day [23,27]. GPB is rarely useful in the presence of an indwelling tracheostomy tube. The safety and versatility afforded by GPB are key reasons for tube decannulation or avoidance of tracheostomy in favor of NIV and MAC. This frees patients from the fear of sudden ventilator failure or accidental ventilator disconnection [23,27,29].

Oximetry Monitoring and Feedback Protocol

For a hypercapnic patient with oxyhemoglobin desaturation due to chronic alveolar hypoventilation or for the patient being weaned from tracheostomy ventilation, introduction to and use of mouthpiece or nasal NIV are facilitated by

oximetry feedback. An SpO₂ alarm set at 94% signals the patient to maintain normal SpO₂ by taking deeper breaths and to maintain SpO₂ above 94% all day [10]. When it is no longer possible to achieve this by unassisted breathing, it is done by mouthpiece or nasal NIV. With advancing disease and muscle weakness, the patient can require increasing periods of daytime NIV to maintain normal SpO₂ and intact central ventilatory drive.

Continuous SpO₂ feedback is especially important during respiratory tract infections. The cough of infants and small children who can never sit is inadequate to prevent chest cold–triggered pneumonia and acute respiratory failure. MAC is used for any dip in SpO₂ below 95%. When NIV is used continuously, such dips are usually due to bronchial mucous plugging rather than to hypoventilation, and if the mucus is not quickly cleared, atelectasis and pneumonia can quickly result. Thus, patients are instructed to use NIV and MAC to maintain normal SpO₂ to avert pneumonia and respiratory failure. For adults with infrequent chest colds, rapid access to MAC may be all that is necessary.

Potential Treatment Complications

Abdominal distention tends to occur sporadically in NIV users. The air usually passes as flatus once the patient is mobilized in the morning. When it is severe, however, it can increase ventilator dependence and necessitate burping the air out by opening a gastrostomy or nasogastric tube.

Despite aggressive lung mobilization and expansion three times daily, often to above 60 cm H₂O pressures and along with NIV support for more than 50 years in many cases, we have had one case of pneumothorax in more than 1000 NIV users [30]. Although it is often described as a complication of or limiting factor for NIV, secretion encumbrance most often results from failure to use MAC.

ICD-9 Code

714.0 Rheumatoid arthritis

ICD-10 Code

M06.9 Rheumatoid arthritis

Definition

Rheumatoid arthritis is a chronic inflammatory disorder that primarily affects joints but may also have prominent extra-articular features. The arthritis is classically symmetric and affects the peripheral joints. The prevalence of rheumatoid arthritis is approximately 1% in white individuals, and it affects women about 2 to 2.5 times more often than men, which may be related to the effect of sex hormones, such as estrogen, in regulating the immune response [1]. Peak incidence of rheumatoid arthritis is in the third and fourth decades, although the disease affects all ages and individuals from all racial and ethnic groups [2–4]. Classification criteria are available for rheumatoid arthritis and may be helpful in the evaluation of patients (Table 151.1). Many patients with early disease, however, may not fulfill these criteria [5].

Symptoms

Rheumatoid arthritis is a systemic disease, and symptoms vary according to the system involved [6–8].

General

Morning stiffness is a prominent feature of rheumatoid arthritis. Unlike the brief stiffness (5 to 10 minutes) that occurs in patients with osteoarthritis, the morning stiffness in rheumatoid arthritis may last for hours. Fatigue and generalized malaise are also common complaints.

Joint

Patients present with joint pain and swelling as well as loss of joint function, which may be due to joint inflammation or structural damage from cartilage destruction and bone erosion. A Baker cyst can develop and cause pain or swelling of the popliteal fossa. If the cyst ruptures, it may cause pain, swelling, and erythema of the calf. If the cricoarytenoid joint is involved, patients may complain of laryngeal pain, hoarseness, or difficulty in swallowing.

Eye

Up to one third of patients will complain of dry eyes (keratoconjunctivitis sicca). These patients may also complain of foreign body sensation, burning, or discharge. Patients with episcleritis will complain of red, painful eyes.

Skin

Patients may note small, painless subcutaneous nodules, mainly over the extensor surfaces. Rheumatoid vasculitis will cause a rash that may lead to ulceration. Patients with vasculitis may also complain of discoloration around the fingertips (digital infarcts).

Neurologic

Numbness and tingling are common symptoms of nerve involvement. Nerve entrapment may result from joint inflammation. The most common site is at the wrist, where median nerve involvement may cause carpal tunnel symptoms. Mononeuritis multiplex is the result of vasculitis and is manifested as weakness, numbness, or tingling in discrete nerve distributions (e.g., femoral, peroneal, or radial nerve, causing proximal leg weakness, footdrop, or wristdrop). Cervical spine instability may lead to myelopathy, causing sensory symptoms and weakness, most commonly in the upper extremities. This can occur in the absence of neck pain in patients with long-standing rheumatoid arthritis.

Cardiac

The incidence and prevalence of coronary artery disease are increased in any type of chronic inflammatory disorder, and this is especially evident in rheumatoid arthritis. Thus patients may present with complaints of chest pain,

Table 151.1 Classification Criteria for Rheumatoid Arthritis*

Criterion	Definition
Morning stiffness	Morning stiffness in or around the joints lasting at least 1 hour before maximal improvement
Arthritis of three or more joint areas	Soft tissue swelling or fluid in at least three joints observed by a clinician The 14 possible joints include right and left proximal interphalangeal, metacarpophalangeal, wrist, elbow, knee, ankle, and metatarsophalangeal joints.
Arthritis of the hand joints	At least one area swollen in a wrist, metacarpophalangeal, or proximal interphalangeal joint
Symmetric arthritis	Simultaneous involvement of the same joint areas on both sides of the body Involvement of the small joint groups (metacarpophalangeal joints, proximal interphalangeal joints, and metatarsophalangeal joints) is acceptable without absolute symmetry.
Rheumatoid nodules	Subcutaneous nodules occurring over bone prominences, extensor surfaces, or juxta-articular regions These must be observed by a clinician.
Serum rheumatoid factor	Abnormal amounts of serum rheumatoid factor by any method for which the result has been positive in <5% of normal control subjects
Radiographic changes	Posteroanterior hand and wrist films that demonstrate erosion or unequivocal bone decalcification localized in or most marked adjacent to the involved joints

*A patient is said to have rheumatoid arthritis if he or she satisfies at least four of the seven criteria. Criteria one through four must have been present for at least 6 weeks.

FIGURE 151.1 The boutonnière deformity, involving hyperextension of the distal interphalangeal joint with flexion of the proximal interphalangeal joint, is caused by a derangement of the extensor mechanism—typically a rupture of the central extensor tendon at its insertion in the middle phalanx. Early diagnosis and prolonged splinting of the proximal interphalangeal joint in extension are necessary for successful treatment of this difficult injury. (From Concannon MJ. *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

FIGURE 151.2 The swan-neck deformity (recurvatum) involves hyperextension of the proximal interphalangeal joint with flexion of the distal interphalangeal joint. This is caused by a derangement in the extensor mechanism, with a dorsal migration of the lateral bands. (From Concannon MJ. *Common Hand Problems in Primary Care*. Philadelphia, Hanley & Belfus, 1999.)

shortness of breath, diaphoresis, and other symptoms consistent with cardiac ischemia. Prevalence of angina in patients with rheumatoid arthritis may be less because of the relative inactivity. Other cardiac manifestations of rheumatoid arthritis include myocarditis, pericarditis, atrioventricular block, and cardiac rheumatoid nodules. Pericardial involvement is usually asymptomatic.

Pulmonary

Pleural inflammation or nodulosis may produce typical symptoms of pleurisy. Shortness of breath may occur secondary to pleural or interstitial disease.

Physical Examination

All joints are examined for swelling, warmth, effusion, range of motion, and deformity. Fingers, feet, wrists, and knees are most commonly involved. The distal interphalangeal joints are usually spared. In rare cases, patients will present with monoarthritis (involvement of a single joint). Rheumatoid nodules are present in about 30% of patients and occur over bone prominences, over extensor surfaces, or in juxta-articular regions [6].

In the hands, early rheumatoid arthritis causes fusiform swelling at the proximal interphalangeal joint. Chronic inflammation may lead to subluxation of the metacarpophalangeal joints with ulnar deviation of the fingers. Damage to collateral ligaments at the proximal interphalangeal joints results in the classic boutonnière (proximal interphalangeal joint flexion and distal interphalangeal joint hyperextension) and swan-neck (proximal interphalangeal joint hyperextension and distal interphalangeal joint flexion) deformities (Figs. 151.1 and 151.2).

Symmetric wrist swelling is usually present. Subluxation results from synovitis and weakening of the ligaments and causes prominence of the ulnar styloid.

Inflammation of the synovial tendon sheath (tenosynovitis) may occur in the flexor or extensor tendons of the fingers. Examination reveals that passive motion is greater than active motion. Crepitus is often felt when the examiner's hands are placed over the tendon sheaths and the fingers

are flexed and extended. If the patient has a trigger finger, placement of one finger over the flexor tendon while the affected finger is flexed and extended will allow palpation of a nodule.

Elbow involvement is common. In early disease, inflammation and effusion cause decreased extension. Effusions can be palpated in the para-olecranon groove. In some cases, there may be pressure on the ulnar nerve. With chronic inflammation and erosion of the cartilage between the radius and ulna, loss of elbow extension and flexion occurs. Rheumatoid nodules are often found over the extensor aspect of the proximal ulna. The olecranon bursa may be enlarged and filled with fluid or nodules.

The shoulder may be involved in rheumatoid arthritis. Effusions are best seen on the anterior aspect of the shoulder below the acromion. Evaluation of rotator cuff strength is important because inflammation of the rotator cuff may result in tendinous destruction. The biceps tendon may rupture, causing a bulge in the biceps when it is flexed against resistance.

The cervical spine may have decreased range of motion or pain with range of motion. Patients with suspected cervical instability should have a thorough neurologic examination, checking for upper motor neuron findings. Patients with cord involvement may demonstrate paresthesias, weakness, or pathologic reflexes. Tingling paresthesias descending the thoracolumbar spine on flexion of the cervical spine are called Lhermitte sign.

The hip joint is deep, limiting evaluation for synovitis and effusion. An inflamed hip will cause groin pain on active and passive range of motion. Patients may walk with an antalgic gait, rapidly taking weight off the affected leg, or shorten their stride length. Pain in the hip may also result from trochanteric bursitis. Application of pressure over the lateral hip region reproduces the pain from the trochanteric bursa. Lateral hip pain and lack of groin pain distinguish trochanteric bursitis from joint inflammation. Iliopsoas bursitis may result in an inguinal mass.

The knee is commonly involved in rheumatoid arthritis. Small effusions can be detected by looking for a “bulge” sign. For the performance of this maneuver, the patient should be lying down. With one hand, the clinician makes an upward stroke to depress the medial synovial pouch. A downward stroke on the lateral aspect of the knee will result in a bulge of the medial pouch if a small effusion is present. A ballottable patella (patellar tap) indicates a larger effusion. Baker cyst occurs as an extension of synovial fluid from the joint cavity. The cyst causes fullness in the popliteal fossa that can be seen when the patient is standing with his or her back facing the clinician. Erythema and swelling of the calf may be seen if the Baker cyst has ruptured. Evaluation for hemorrhage below the malleoli of the ankle (the “crescent” sign) can distinguish this from thrombophlebitis.

The ankle may have synovitis, effusion, or decreased range of motion in the patient with rheumatoid arthritis. Involvement of the hindfoot (subtalar and talonavicular joints) may result in valgus deformity and flatfoot. Metatarsophalangeal joint involvement is common. Synovitis causes pain and fullness with palpation. Hallux valgus deformity is also common. Progressive disease causes dorsal dislocation of the metatarsophalangeal joints and claw toes.

Table 151.2 Criteria for Classification of Functional Status in Rheumatoid Arthritis

Class I	Able to perform all activities of daily living (self-care, vocational, and avocational)
Class II	Able to perform self-care and vocational activities, but limited in avocational activities
Class III	Able to perform usual self-care activities, but limited in vocational and avocational activities
Class IV	Limited in all activities of daily living (self-care, vocational, and avocational)

Functional Limitations

Functional limitations depend on the location and severity of joint and extra-articular involvement. There may be limitations or pain with upper extremity movements or lower extremity motions, including gait. Criteria for the assessment of functional status have been established (Table 151.2) and are based on activities of daily living, including self-care (e.g., dressing, feeding, bathing, grooming, and toileting) and vocational (e.g., work, school, and homemaking) and avocational (e.g., recreational and leisure) activities [10].

Whereas radiologic changes have limited value in determining functional impairment and quality of life, disability from rheumatoid arthritis has been directly attributed to joint damage, disease activity, pain, and depressive symptoms [11]. Patients with rheumatoid arthritis may have less disability conviction than those with other problems, such as low back pain.

Diagnostic Studies

Laboratory histologic findings and radiographic findings may be suggestive of rheumatoid arthritis, but no test is diagnostic of the disease [6,12] (Figs. 151.3 and 151.4). Rheumatoid factor is present in the serum of 85% of patients [8]. However, because rheumatoid factor is often present in other inflammatory conditions, such as systemic lupus erythematosus, primary Sjögren syndrome, and chronic osteomyelitis, much debate exists about its utility in the diagnosis of rheumatoid arthritis as a result of low specificity [13]. Anti-cyclic citrullinated peptide antibodies have shown more promise as potential biologic markers because of sensitivities of 70% to 80% and specificities of 95% to 98% in patients with established rheumatoid arthritis [14]. Normochromic, normocytic anemia consistent with chronic disease is often found, and the degree of anemia often correlates with disease activity. Acute phase reactants, such as erythrocyte sedimentation rate, C-reactive protein concentration, and erythrocyte and platelet counts, are elevated. Eosinophilia may be found in patients with extra-articular manifestations. Patients with Felty syndrome (rheumatoid arthritis, splenomegaly, and leukopenia) exhibit low white blood cell counts and may have thrombocytopenia. A variant of Felty syndrome has been described in which patients have large granular lymphocytes in blood and bone marrow in addition to neutropenia. Liver enzymes including aspartate transaminase and alkaline phosphatase are often elevated in patients with active disease.

Evaluation of fluid taken from an affected joint will show an inflammatory cell count (more than 2000 white blood cells). Joint fluid should always be sent for culture to rule out infection and evaluated under a polarized microscope to

FIGURE 151.3 Advanced rheumatoid arthritis—hand and wrist. Bony ankylosis at the wrist, penciling of the distal ulna, and marked erosive changes at the metacarpophalangeal joints with ulnar deviation of the fingers are classic findings of rheumatoid arthritis. Also note the more severe involvement of the carpus and metacarpophalangeal joints; interphalangeal joints are typically less severely affected. (From Katz DS, Math KR, Groskin SA. *Radiology Secrets*. Philadelphia, Hanley & Belfus, 1998.)

FIGURE 151.4 Atlantoaxial subluxation—rheumatoid arthritis. There is marked widening of the space between the anterior arch of the atlas (A) and the margin of the dens (D). (From Katz DS, Math KR, Groskin SA. *Radiology Secrets*. Philadelphia, Hanley & Belfus, 1998.)

exclude crystal disease. If pleurocentesis or pericardiocentesis is necessary, the fluid has a low complement concentration, a high protein concentration, and a predominance of lymphocytes. The glucose concentration is characteristically extremely low or may even be absent.

Characteristic changes on joint radiographs include periarticular osteopenia and marginal erosions. Early in the disease, joint films may be normal. Baseline hand and wrist films may aid in diagnosis and can be used to follow disease progression. Flexion and extension views of the cervical spine may demonstrate erosion of the odontoid and atlantoaxial subluxation. Pulmonary nodules or interstitial fibrosis can be seen on the chest radiograph. Echocardiography often reveals a small pericardial effusion, valvular thickening, or aortic root dilation, but these are most often asymptomatic. Electrocardiography may reveal conduction abnormalities due to involvement of the cardiac conduction system by rheumatoid nodules.

Differential Diagnosis

- Crystal-induced arthritis
- Gout
- Pseudogout
- Spondyloarthropathies
- Psoriatic arthritis
- Ankylosing spondylitis
- Enteropathic arthritis

Treatment

Initial

Nonsteroidal anti-inflammatory drugs are effective in some patients.

For patients with inadequate response to nonsteroidal anti-inflammatory drugs or poor prognostic indicators, disease-modifying antirheumatic drugs (DMARDs) should be initiated. Poor prognostic factors include high-titer rheumatoid factor, early presence of bone erosion, many affected joints, extra-articular involvement, and considerable degree of physical disability at disease onset [9,15].

DMARDs that are prescribed include antimalarials, intramuscular administration of gold, sulfasalazine, azathioprine, methotrexate, leflunomide, cyclosporine, and cyclophosphamide [15,16]. Anticytokine therapies include the anti-tumor necrosis factor- α agents etanercept, infliximab, and adalimumab and the interleukin-1 receptor antagonist anakinra. Other biologic agents currently available include abatacept (CTLA4-Ig) and rituximab, which is a B cell-depleting monoclonal antibody. Several studies support the use of combination DMARD therapy [17]. Anti-tumor necrosis factor- α agents used in combination with small-molecule DMARDs such as methotrexate will often halt disease activity and radiologic progression of joint destruction [18]. Corticosteroids can be very useful and can be administered systemically as a bridge to therapy with DMARDs or intra-articularly for monoarticular or oligoarticular involvement.

Patients who have persistent pain due to structural damage may need treatment specifically for the pain, with different medications. Depending on the patient, one may need to consider analgesics, anti-inflammatories, opioids, opioid-like drugs (tramadol), and neuromodulators to include antidepressants, anticonvulsants, and muscle relaxants [19].

Rehabilitation

Once the diagnosis is confirmed, it is important to work together with a rheumatologist to prescribe the most optimal

rehabilitation treatment program. Static exercise regimens to maintain strength while protecting inflamed joints from adverse stress are recommended. Appropriate referrals to occupational or physical therapists for more specific treatment and splinting can be initiated by a physician, with close follow-up to determine whether the patient needs modifications or changes in the treatment program as the disease progresses. The physician can also address issues of pain, return to work, and maintenance of function important to the patient's lifestyle.

The role of occupational and physical therapy may be different in early or established disease and end-stage disease [20,21]. In early disease, occupational therapy is directed toward education of the patient about how to minimize joint stress in performing activities of daily living. Splints may be used to provide joint rest and to reduce inflammation during the acute inflammatory phase. Splints may also allow functional use of joints that would otherwise be limited by pain. However, not all clinicians advocate splints as they can facilitate more joint stiffness if they are used routinely. Paraffin baths can provide relief of pain and stiffness in the small joints of the hands. Contrast baths are used to increase superficial blood flow, although the benefit for patients with rheumatoid arthritis is not clear [22]. In end-stage disease, the occupational therapist plays an important role, providing aids and adaptive devices, such as raised toilet seats, special chairs and beds, and special grips that can assist in self-care. By maximizing one's functional ability, the occupational therapist can help prevent other physical or psychological problems [23]. Outcomes can include improvements in self-care, productivity at home and at work, and leisure time enjoyment [24].

Physical therapy can be helpful in reducing joint inflammation and pain. The therapist may employ a variety of techniques, including the application of heat in conjunction with passive stretch or cold for inflamed joints. Water exercise (hydrotherapy) is used to increase muscle strength without joint overload. In patients with foot involvement, small alterations to footwear or inserts may decrease pain and provide a more normal gait. In end-stage disease, the goals of therapy are to reduce joint inflammation, to enhance flexibility, to improve the function of damaged joints, and to improve strength in surrounding muscles and maintain a level of physical fitness.

Local immobilization may be used to reduce inflammation and pain. Nonfixed contractures may be prevented or improved with periods of splinting combined with goal-oriented exercise. Muscle strength and overall conditioning may be improved by static, range of motion, and relaxation exercises. In recent years, aerobic and weight-bearing exercises have been used without detrimental effect to the joints. These dynamic exercises are more effective in increasing muscle strength, range of motion, and physical capacity [25]. However, high-intensity weight-bearing exercises have been shown to accelerate joint destruction in individuals with preexisting extensive large-joint damage from rheumatoid arthritis [26]. Thus the exercise prescription must be appropriately tailored to the degree of disease present in each patient. The motivation and encouragement provided by the physician and therapist should not be underestimated. In one study, the communication skills and disease-specific knowledge exhibited by the therapists were most important in managing the patient's disease.

The investigators also identified a need for therapists to have a good understanding of the disease process and to understand the role of a multidisciplinary team in treating the patient [27]. Some therapists may require more professional development to confidently educate and treat this patient population. In another study by O'Brien [28], there was significant improvement in arm function with patients who did home strengthening exercises versus stretching and education alone. Resistance exercise has been shown to be safe and efficacious as it improves isokinetic, static, and grip strength [29]. Community aquatic programs for arthritis help reduce stress on weight-bearing joints and provide some general conditioning [30,31].

Procedures

For monarticular or oligoarticular involvement, local steroid injection may be used when oral medications fail to control joint inflammation. If there is electrodiagnostically confirmed carpal tunnel syndrome, focal steroid injections may be helpful. If the neurophysiologic studies confirm more sensory axonal loss or motor involvement, surgical decompression may be recommended [32]. Ultrasonography is recognized as useful diagnostically, because a skilled examiner can differentiate tendinopathy from bursitis and determine whether there is any entrapment of these structures with movement. The goal of any diagnostic procedure is increase the specificity for the diagnosis. Sonography is dynamic and can be more specific than other diagnostic imaging in the hands of a skilled sonographer [33]. There is increasing use of ultrasonography for needle placement during procedures to ensure injection into the affected joints [34]. The goals of any procedure are to maintain the patient's functional level, to minimize pain, and to try to prevent more debility from the disease by slowing the progression or treating associated problems that impair function.

Surgery

Orthopedic intervention includes joint reconstruction (arthrodesis) or replacement (arthroplasty) (Fig. 151.5). For hand patients with low-demand activities, arthroplasty

FIGURE 151.5 Hinged silicone prosthesis with grommets. Radiograph of implanted prostheses at the metacarpophalangeal joints of the index, middle, ring, and little fingers on the right hand. (From Weinzeig J. *Plastic Surgery Secrets*. Philadelphia, Hanley & Belfus, 1999.)

FIGURE 151.6 Subluxation of vertebrae in rheumatoid arthritis. The abnormal movement between vertebrae due to laxity of ligaments becomes more apparent in flexion of the cervical spine. Lateral flexion-extension views are requested if subluxation of cervical vertebrae is suspected. The radiograph in **A** is taken in the neutral position, and the one in **B** is taken in flexion. The arrowheads mark the distance between the anterior surface of the odontoid process and the posterior surface of the arch of the atlas. This space is increased in flexion because of subluxation of the arch of the atlas on the second vertebra. The arrows show anterior slippage of the third cervical vertebra on the fourth. In a normal cervical spine, the posterior surface of vertebral bodies forms a smooth curve that is convex anteriorly (lordosis). This curve is disturbed and a step-like deformity is seen (arrows) at the posteroinferior angle of the upper vertebra and the posterosuperior angle of the lower vertebra in subluxation. (From Mehta AJ. *Common Musculoskeletal Problems*. Philadelphia, Hanley & Belfus, 1997.)

may be helpful, whereas more active patients may do better with arthrodesis [35]. For patients with involvement of larger joints, arthroplasty can significantly improve one's activity level and lifestyle. Some patients may require tendon repair or synovectomy. Any surgical procedure should take into consideration the functionality of the entire upper or lower extremity [36]. Patients with suspected or confirmed cervical spine involvement will need special consideration and handling during intubation for anesthesia (Fig. 151.6). Surgical cervical spine stabilization may be considered if the patient has neurologic symptoms.

Potential Disease Complications

The most common complication is joint destruction with subsequent decreased functional use of affected joints. Neuropathy may be due to entrapment, pressure, or deposition of amyloid. Cervical instability can lead to myelopathy. Irregular bone edges may result in tendon rupture. Nodules may break down and ulcerate. Skin ulcerations may also occur in pressure points in the immobilized patient. The kidneys and gastrointestinal tract may be sites of deposition in patients who develop secondary amyloidosis. Scleritis may result in scleromalacia. As previously mentioned, cardiovascular disease is almost always present in aggressive or untreated cases.

Potential Treatment Complications

Medication side effects vary according to the drug (Table 151.3) [16].

Overly aggressive physical or occupational therapy can cause increased joint inflammation, joint deformity, and pain.

Table 151.3 Side Effects of Medications Used to Treat Patients with Rheumatoid Arthritis

Medication	Side Effects
Nonsteroidal anti-inflammatory drugs	
Traditional	Dyspepsia, ulcer, or bleeding Renal insufficiency Hepatotoxicity Rash Inhibit platelet function
Cyclooxygenase-2 inhibitors	Same as traditional nonsteroidal anti-inflammatory drugs, but gastrointestinal side effects occur less often No platelet effect
Glucocorticoids	Increased appetite, weight gain Cushingoid habitus Acne Fluid retention Hypertension Diabetes Glaucoma, cataracts Atherosclerosis Avascular necrosis Osteoporosis Impaired wound healing Susceptibility to infection
Antimalarials	Dyspepsia Hemolysis (glucose-6-phosphate dehydrogenase-deficient patients) Macular damage Abnormal skin pigmentation Neuromyopathy Rash
Gold	Myelosuppression Proteinuria or hematuria Oral ulcers Rash Pruritus

Table 151.3 Side Effects of Medications Used to Treat Patients with Rheumatoid Arthritis—cont'd

Medication	Side Effects
Etanercept	Injection site reaction Exacerbation of infection
Cyclosporine	Renal insufficiency Hypertension Anemia
Sulfasalazine	Myelosuppression Hemolysis (glucose-6-phosphate dehydrogenase-deficient patients) Hepatotoxicity Photosensitivity, rash Dyspepsia, diarrhea Headaches
Azathioprine	Oligospermia Myelosuppression Hepatotoxicity Pancreatitis (rarely) Lymphoproliferative disorders (long-term risk)
Methotrexate	Hepatic fibrosis, cirrhosis Pneumonitis Myelosuppression Mucositis Dyspepsia Alopecia
Leflunomide	Increased rheumatoid nodules Hepatic fibrosis, cirrhosis Myelosuppression Dyspepsia Alopecia
Infliximab	Infusion reaction Exacerbation of infection
Cyclophosphamide	Dyspepsia, diarrhea Myelosuppression Alopecia Hemorrhagic cystitis Ovarian and testicular failure Teratogenicity Malignant neoplasia Opportunistic infection

Definition

Scoliosis

Scoliosis (Fig. 152.1) is a structural or postural deformity of the spine that results in a lateral (coronal) deviation or curve. Scoliosis is associated with rotation of the vertebral bodies located within the curve. It may also be associated with an arm or leg length difference, particularly in cases of idiopathic or congenital scoliosis.

Scoliosis is most commonly idiopathic, degenerative, or a result of vertebral anomalies. Less prevalent is scoliosis consequent to disease-related or iatrogenic causes. Growth asymmetry at the vertebral end plate, rib, and pelvic growth

FIGURE 152.1 A, Examples of scoliosis curve patterns. B, Scoliosis.

centers can result in scoliosis and progression of a scoliotic curve [1,2].

Scoliosis affects between 3% and 30% of the population; about 0.25% require treatment [3]. The incidence of scoliosis increases with age [4] (Table 152.1). The scoliotic curve may be congenital; appear during infancy (infantile scoliosis); or develop in childhood (juvenile scoliosis), adolescence (adolescent scoliosis), or adulthood. When the diagnosis of scoliosis is made in an adult patient, the curve is identified as either adult onset (degenerative) or adult presenting (a previously undiagnosed idiopathic adolescent curve).

There is increasing evidence that idiopathic curves can result from genetic or epigenetic factors. Gene candidates have been identified in a genome-wide association study. Statistical associations with scoliosis exist for gene polymorphisms (interleukin receptor and vitamin D receptor genes; *ATRX* gene; and chromosomes 6, 9, 16, and 17) [5–8]. All are associated with idiopathic curves. Epigenetic factors that might contribute to the development of scoliosis relate to maternal age, spinal cord injury before the age of 5 years (96% prevalence of scoliosis), DNA methylation, and transient fetal hypoxia [9–12]. These are only associations, and at this time any causality or mechanism of action is unclear.

Other types of scoliotic curves can begin with degenerative changes in the spine, congenital malformation of the vertebrae (usually incomplete fusion—butterfly vertebrae

or hemivertebrae), tumor, neuromuscular or connective tissue disease, trauma, surgery, or radiation therapy.

Kyphosis

Thoracic kyphosis is an excessive sagittal deviation in thoracic spine alignment, a dorsal apex curve exceeding 40 degrees. Possible causes include osteoporotic compression fractures (note that most of these fractures are asymptomatic and unidentified), direct trauma, chronic kyphotic posture, tumor, radiation therapy [13], and Scheuermann disease. A resulting wedge deformity of the vertebral bodies produces the malalignment. Animal studies suggest that gestational and neonatal hypovitaminosis D or alterations in calcium and phosphorus concentrations in neonatal feedings can play a role in the development of pathologic kyphosis. The incidence of kyphosis in animals studied with maternal vitamin D deficiency during gestation or with low calcium and phosphorus feed content was 32%. No similar humans studies have been published. Earlier presentation of the kyphotic deformity was seen in cases of maternal hypovitaminosis D [14].

Cervical kyphosis is pathologic. Infection (particularly tuberculosis), tumor, abnormal development of the cervical vertebrae, trauma, and advanced degenerative disease of the spine can produce cervical kyphosis. Kyphosis related to trauma (including laminectomy)

Table 152.1 Age at Presentation and Common Causes of Scoliosis

Time of Presentation	Most Common Causes	
Congenital	Abnormalities of development, vertebral body	Failure of fusion or development: hemivertebrae, butterfly vertebrae (types 1-4) Abnormal differentiation (especially weeks 1-6)
Infantile (0-3 years)	Developmental, associated with abnormal development of other systems Postural Idiopathic Related to disease or trauma	Genetic or epigenetic (?) Trauma (especially spinal cord injury) Tumor (neurofibroma)
Juvenile (4-9 years)	Idiopathic Related to disease or trauma	Genetic (?) Neuromuscular disease Connective tissue disease Tumor (neurofibroma) Metabolic disease
Adolescent Adult	Idiopathic Adult presenting, idiopathic Adult, degenerative	Trauma (especially spinal cord injury) Genetic (?) Progression of idiopathic adolescent curve Lithesis Spondylosis Facet arthropathy Laminectomy Radiation therapy Tumor (primary, metastatic)
	Adult, disease or treatment related	

or advanced degenerative changes in the cervical spine (due to disease such as rheumatoid arthritis or the mechanical changes that can occur over time) becomes more prevalent with advancing age. The most common tumors are manifested early in life as osseous or neural extramedullary masses. They include (in order of decreasing frequency) chordoma, bone cyst, Ewing sarcoma, meningioma, schwannoma, and neurofibroma [15]. As a feature of the congenital cervical vertebral dysmorphic syndromes, cervical kyphosis is noted in the following syndromes: Down, Morquio, Goldenhar, Klippel-Feil, Stickler, Williams, and Larsen [16].

Symptoms

Scoliosis

Scoliosis is usually asymptomatic. If symptoms are present, they generally are produced by scoliosis as it directly relates to the location and severity of the curve. Large or highly rotated curves can produce pain and have the potential to produce symptoms related to the cardiopulmonary or nervous systems. Curves that exceed 60 to 80 degrees begin to affect other organ systems. They can produce shortness of breath or poor endurance due to decreased lung capacity. If there is pressure on nerve roots or the spinal cord, the patient may experience paresthesia or hypesthesia, weakness, and bowel or bladder involvement.

There is some controversy as to whether cosmetic changes related to thoracic scoliosis contribute to low self-esteem, anxiety, and depression (particularly in adolescents). Quality of life indices do not differ for adults by the age of 30 years [17].

Musculoskeletal pain may occur in performing activities of daily living that require a full active range of shoulder motion, such as overhead or extended reach

activities. There may be upper back and neck pain in lifting or carrying because of strain of the scapular or shoulder muscles.

Kyphosis

Thoracic kyphosis is usually asymptomatic. If symptoms do appear, they are commonly associated with intermittent aching back pain and stiffness that are most prominent at the apex of the curve. Compensatory lumbar lordosis can be associated with low back pain.

Kyphosis with a wide scapular spread and shoulder and head protraction restricts both shoulder range of motion and the ability to look upward. When the ability to compensate for this with cervical or lumbar motion is compromised, kyphosis results in difficulty in performing overhead activities. Patients with cervical kyphosis may also complain of neck pain and the inability to look upward.

Physical Examination

Scoliosis

Scoliosis is usually apparent on inspection, although small thoracic curves with minimal rotation or a small lumbar curve can be difficult to detect. Have the patient bend forward (Adam forward bend test). If pelvic and lower extremity asymmetries affect the appearance of the back, minimize these by examining the patient in a seated position. Vertebral body or rib rotation associated with scoliosis is most readily seen when the patient bends forward. The tilt of the back, reflective of the angle of rotation, can be quantified by the use of a type of level, the scoliometer. The level is placed on the forward bent back in the area of maximum tilt and measures that angle. In idiopathic thoracic scoliosis, an angle of 7 degrees

roughly corresponds to a scoliotic curve between 10 and 20 degrees.

Scoliosis can produce apparent asymmetry of breast size, asymmetry of the waist fold contour, asymmetric appearance of arm or leg length, or unequal iliac crest and shoulder height. A true leg length discrepancy exceeding 2.2 cm is indicative of asymmetric growth and possible scoliosis [18].

Serial assessment of scoliosis is advisable. The frequency of evaluation varies with curve parameters and treatment but is generally between 6 and 12 months, more frequently with curves that are progressing or being treated. These assessments focus on the degree of curvature, location and extent of the curve, degree of rotation, degree of skeletal maturity, flexibility of the curve, height, vital capacity, and expiratory pulmonary function tests.

Patients with degenerative scoliosis should be examined for neurologic deficits. Lower extremity strength, sensation, and reflexes can be impaired if the curvature exceeds 40 degrees.

Congenital vertebral malformations arise during the first 6 weeks of gestation. Symptoms and signs may be identified that relate to other systems in early development at that same time, particularly cardiac and renal.

Kyphosis

Increased thoracic kyphosis displaces the head and neck forward, and this forward displacement can be measured as an occiput to wall distance. A compensatory increase in lumbar lordosis can occur. These are apparent on inspection. The rounding of the back will not fully correct with trunk extension in a prone position, but the degree to which the curve decreases with active extension of the neck and upper back should be used as a benchmark for subsequent evaluations. Severe cervical kyphosis can produce a chin on chest appearance, but smaller curves are also readily apparent. Thoracolumbar and lumbar kyphoses are less easily identified on inspection. Prominence of the spinous processes can indicate lower spine kyphosis [19]. Kyphosis-associated scoliosis will be present in about one third of patients [20]. Restrictions in active trunk and neck extension can result from either deformity or pain. Tightness of the pectoral muscles is common.

A neurologic examination should be performed if there are radicular or myelopathic symptoms.

Functional Limitations

The functional limitations related to scoliosis and kyphosis result from the loss of spinal motion. Restriction in upper back extension can reduce upward gaze and affect driving or cause discomfort in lying prone or swimming in a prone position. Loss of shoulder range of motion, particularly forward flexion and abduction, can result from a decreased range of scapular excursion over the scoliotic or kyphotic thorax. This impedes overhead activities of daily living. When present, pain and stiffness can limit sitting, standing, or walking tolerance.

Disruption of spinal balance displaces the center of gravity, particularly with large uncompensated curves.

This increases the energy costs for standing and ambulation. It can also impair balance. With severe deformity and cardiopulmonary compromise, endurance is diminished. Cosmetic deformities that affect self-image or self-esteem can lead to social isolation. Age-related changes in anatomy and physiology can compound the impairments and restrict mobility or cause disability associated with the activities of daily living.

Diagnostic Studies

Standing anteroposterior and lateral radiographs are the standard diagnostic tests used to evaluate scoliosis and kyphosis. Radiographs can reveal congenital abnormalities of the vertebral body, Scheuermann disease, or lateral vertebral body wedging [21]. Bending or supine radiographs are not usually obtained but can help determine the flexibility of the curve. Non-weight-bearing radiographs and serial radiographs, both in the brace and out of the brace, may offer some advantage in estimating possible correction, actual correction, and the effectiveness of bracing [22].

Rib-vertebral angle and space available for lung (reported to be useful in cases of infantile scoliosis) are less common but available x-ray assessments. The difference in angle magnitude or ratio of angles between the convex and larger concave rib-vertebral angles in the thorax can be sensitive indicators of change [23,24].

X-ray measurement of the scoliotic curve is commonly done by the Cobb method. The Cobb angle is the angle at the intersection of lines drawn perpendicular to the vertebral end plates that frame the curve—those with the maximal tilt (Fig. 152.2).

Radiographs can demonstrate vertebral body rotation and the status of growth centers in the ilium, vertebrae, and humerus. The degree of vertebral body rotation is gauged by the deviation from midline of the spinous process or fullness of the pedicle silhouette. Rotation is graded 0 (no rotation) to 4 (rotation of 90 degrees or more). Closure of the growth plates proceeds in a cephalad manner. Because vertebral growth plates are usually not visualized, iliac and femur epiphyses are useful sites for assessing spine growth status. Growth status is graded 0 (no mineralization) to 5 (fusion of the growth plate). Radiographs can help assess the growth or degenerative status of the spine, useful information for determining a plan of care.

Magnetic resonance imaging can identify an unsuspected pathologic process, for example, a neurofibroma, diastematomyelia, or tethered cord. Magnetic resonance imaging is recommended before surgery as an otherwise undetectable spinal cord abnormality is present in about 10% of cases slated for surgery [25].

Bone scans can help exclude discitis or tumor as a cause of pain or spinal deformity. Bone densitometry demonstrates increased density on the convex side of the curve. This occurs even in osteoporotic patients [26]. Pulmonary function testing, particularly volume and expiratory studies, should be performed when curves exceed 50 degrees. Genetic testing for markers associated with scoliosis is available but not useful at this time.

FIGURE 152.2 A, Measurement of idiopathic scoliosis by the Cobb angle. B, Idiopathic adolescent scoliosis. There is a primary thoracic dextroscoliosis (convexity to the right side) measuring 52 degrees and a compensatory lumbar levoscoliosis (convexity to the left side) measuring 47 degrees. Differential Diagnosis

Differential Diagnosis for Spine Deformity

Scoliosis
 Congenital
 Infantile
 Neuromuscular
 Juvenile idiopathic
 Adolescent idiopathic
 Adult presenting
 Idiopathic
 Degenerative (lumbar)
 Kyphosis
 Lateral listhesis
 Spondylolisthesis
 Postural scoliosis
 Spondyloepiphyseal dysplasia tarda
 Congenital vertebral malformation
 Postural kyphosis

Differential Diagnosis for Disease Underlying Spine Deformity

Spina bifida
 Myelomeningocele
 Syringomyelia
 Klippel-Feil syndrome
 Thoracic insufficiency syndrome
 Traumatic brain injury
 Cerebral palsy
 Myopathy
 Muscular dystrophy
 Spinal cord injury
 Spinal muscular atrophy
 Marfan syndrome
 Ehlers-Danlos syndrome
 Friedrich ataxia
 Osteogenesis imperfecta
 Rheumatoid arthritis
 Fracture
 Tumor
 Tuberculosis
 Scheuermann disease

(degree of curvature), particularly if they are “unbalanced” (e.g., a single major curve without a compensatory curve), are likely to progress. Other curves that tend to progress are those with a closely packed configuration (a small number of spinal segments between the apex and ends of the curve), congenital vertebral body malformation, and neuromuscular or lumbar degenerative disease etiology [27].

Lumbar degenerative scoliosis (this includes adult-presenting idiopathic scoliosis with subsequent degenerative change) is most likely to progress when L5 is involved or there are asymmetric changes in the L2-3 or L3-4 disc space.

In general, scoliotic curves that measure less than 20 degrees or kyphotic curves measuring less than 40 degrees are observed rather than treated with bracing or surgery. Observation can be supplemented by an exercise program.

Pain can be treated with bracing or exercise. Anti-inflammatory medication, analgesics, acupuncture, and transcutaneous electrical nerve stimulation may be useful.

There is no clear role for electrical stimulation of paraspinal muscles in the treatment of scoliosis. Treatment of coincident disease, such as osteoporosis, complements the treatment of scoliosis and its attendant symptoms and disability.

Treatment

Initial

The broad categories of treatment for scoliosis and kyphosis include observation, bracing, and surgery. The problems needing treatment fall into the categories of pain, deformity, deficit, and disability.

In all patients, regardless of age, it is important to identify curves that are likely to progress. Curves that are large

Rehabilitation

Exercise is beneficial for general well-being, flexibility, and improvement of posture. There is no clear evidence that exercise is a disease-modifying intervention for idiopathic scoliosis [28]. There is, however, a specific exercise protocol for scoliosis, the Schroth method. These exercises attempt to correct growth imbalances in the back and to improve spinal alignment. There is anecdotal evidence that the

Schroth method is useful in the treatment of small curves, particularly the component exercises of spinal extension, abdominal strengthening, and hamstring stretch. These exercises may also be helpful in treating back pain. Kyphosis may improve with cervicothoracic extension exercise and pelvic tilt to reduce lumbar lordosis, along with stretching and strengthening exercise of the hamstrings, hip flexors, and pectoralis muscles.

Physical therapy and occupational therapy should be prescribed as an appropriate part of a pain management plan as well as to optimize independent mobility and function in activities of daily living.

Bracing is an important part of the rehabilitation intervention when scoliosis is symptomatic or progressive. Scoliotic curves exceeding 20 degrees are 20% to 40% more likely to progress if a brace is not used, as is kyphosis in excess of 40 degrees.

Bracing for scoliosis is most effective for lower thoracic and lumbar curves. In the case of idiopathic adolescent scoliosis, an orthosis has the potential to provide good control. Stabilization of the curve occurs in 42% to 92% of cases, depending on the accuracy of brace prescription and patient compliance. Actual correction (reduction of the coronal deviation and rotation) with bracing, including serial casting, is more likely to happen in cases of infantile or juvenile idiopathic curves than it is for scoliosis at other ages [29].

There are many different orthoses in use, with a plethora of names [30]. The mechanics of bracing varies with brace type. Braces can be static (constant pressure and rigid containment) (Fig. 152.3) or dynamic (movement opposing the spine deviations, facilitated by flexible bands). Braces can work by derotation, three-point pressure correction, or distraction. Braces may need to be worn full-time or at intervals throughout the day (usually at night or during episodes of pain). Selection of the brace with the best control effect and the least discomfort or inconvenience depends on several factors. These factors include curve parameters, such as etiology, location, and rotation of the curve, but also symptoms and likely compliance with prescribed use [31].

In adolescent idiopathic scoliosis, the goal of orthotic treatment is to limit progression of the curve. There is no clear consensus regarding daily brace wear-time. Recommendations range from 8 to 23 hours. Bracing for idiopathic curves in a growing child or adolescent is maintained until the spinal growth centers fuse.

When a brace is used to decrease pain and to improve posture for patients with degenerative scoliosis, the brace is worn when needed. The most commonly prescribed brace is the thoracolumbosacral orthosis, such as a body jacket with wedges or pads. High thoracic and cervical scoliosis and kyphotic curves require a Milwaukee cervicothoracolumbosacral orthosis.

In cases of scoliosis associated with neuromuscular diseases, bracing guidelines are less clear. Bracing may be withheld while the patient is ambulatory. Braces can be useful as a means to delay surgical intervention. If a body jacket is provided, an abdominal window is needed to allow respiratory excursion.

Contoured or custom-molded seating systems that align and support the trunk can be useful in patients with neuromuscular disease. These accommodate the scoliotic curve while allowing the patient to maintain an upright posture

FIGURE 152.3 Body jacket thoracolumbosacral orthosis, posterior opening.

while seated, improving head control and upper extremity function.

Procedures

There are no invasive physiatric procedures for the treatment of scoliosis or kyphosis.

Surgery

The goal of surgery is to stabilize the spine through correction or control of the deformity. Indications for surgical correction of scoliosis or kyphosis include progressive deformity, segmental instability, progressive or new neurologic deficit, and cardiopulmonary compromise. Pain, even when it is refractory to conservative management, is a controversial indication for surgery. Inability to use a brace or severe cosmetic deformity can be an indication for surgery in specific instances.

Scoliosis

A variety of surgical techniques and approaches address the coronal and rotational deformities. There are procedures that provide decompression to relieve scoliosis-related stenosis. There are surgical strategies to preserve or to promote growth of the spine in children and adolescents. Stabilization

of the spine is the primary goal in any surgery, but there are multiple ways to achieve this stability.

Surgery for idiopathic (adolescent, adult presenting) scoliosis addresses the coronal and rotational deformities by derotation or distraction. The spine is stabilized with hardware with or without bone fusion.

Static stabilization of the spine is achieved through fusion. This eliminates any future growth at the fused segment and may not be the procedure of choice for a growing child, for whom dynamic stabilization may be the better option. For these patients, the goal of treatment is to foster balanced growth of the spine. In the youngest patients, a rib cage implant can do this. In cases of infantile or juvenile idiopathic scoliosis, some success with thoracoscopic stapling has been reported [32]. Semirigid rods or cords can be used to control spinal motion while promoting growth [33,34]. Growth rods are lengthened either surgically or magnetically about every 6 months [35]. A similar technique with dynamic stabilization (but without growth rods) that reduces or eliminates the adverse effects associated with static stabilization has also been reported in cases of degenerative scoliosis [36].

Lumbar degenerative scoliosis can be associated with radicular disease. Surgical options in such instances include various degrees of decompression and long (extending above and below the curve) or short fusion. The selection of the procedure is influenced by the location of the scoliosis, but when possible, long fusion is the better option [37,38].

Kyphosis

Various surgical approaches have been used to correct thoracic kyphosis. Combined anterior plus posterior instrumentation with fusion currently provides the highest success rate for lasting correction and pain relief [39].

Potential Disease Complications

Scoliosis and kyphosis can produce pain and reduce joint or segmental motion and result in disability. The deformity can progress and contribute to the development or worsening of spondylosis, facet arthropathy, spondylolysis, and spondylolisthesis. Such changes in spine structure and mechanics correlate well with large angles and angles of rotation at the curve apex [40]. Foraminal, lateral recess, or canal stenosis can occur with signs and symptoms of neurologic compromise. Root entrapment usually occurs on the concave side of the curve (rarely both convex and concave sides). Cauda equina compression has been reported, as has myelopathy [41].

Shortness of breath, poor endurance, and poor activity tolerance due to restrictive lung disease can occur as a complication of scoliotic curves exceeding 40 degrees or kyphosis in excess of 50 degrees.

Potential Treatment Complications

Most treatment complications follow surgery or bracing. Exercise-related complications are uncommon but include overuse conditions of the soft tissues (tendinitis, bursitis, sprain, strain).

Complications of bracing include skin breakdown, dermatitis due to an allergy to the orthotic material, hyperhidrosis,

cutaneous infection, gastroesophageal reflux disease, esophagitis, and altered gastrointestinal motility. There can be shortness of breath, difficulty in sitting, low self-esteem, and altered body image.

Surgical complications include vascular or neurologic injury, pseudarthrosis, infection, graft donor site pain, progressive pelvic obliquity, painful degenerative changes in the segment adjacent to the level of fusion (especially low lumbar or at T11-T12), spine segment instability, hardware prominence or failure, and thromboembolism. Hardware complications include slippage of anchoring hooks, bending or fracture of a rod, wire pull-out, and hardware migration [42]. High complication rates are associated with the placement of growth rods. Progression of the curve is possible despite surgical fixation. The patient with degenerative scoliosis who has undergone otherwise successful surgery may continue to experience pain or restricted mobility and may need revision surgery at a later time.

CHAPTER 153

Spasticity

Joel E. Frontera, MD
Monica Verduzco-Gutierrez, MD

Synonyms

Increased muscle tone
Spastic dystonia

ICD-9 Codes

728.85 Spasm of muscle
781.0 Abnormal involuntary movements
781.92 Abnormal posture
333.2 Myoclonus

ICD-10 Codes

M62.838 Muscle spasm
R25.9 Abnormal involuntary movements
R29.3 Abnormal posture
G25.3 Myoclonus

Definition

Spasticity is commonly defined as a velocity-dependent increase in muscle tone with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex. This means that the faster the passive movement of the limb through its range, the greater the increase in muscle tone. This definition makes spasticity a component of an upper motor neuron syndrome, which is also associated with other findings that include hyperreflexia, clonus, muscle co-contraction, and muscle weakness.

Spasticity can be caused by a variety of upper motor neuron conditions. It is often noted to be a major problem in conditions like spinal cord injury, multiple sclerosis, and traumatic brain injury. It is estimated to affect between 40% and 80% of patients with a spinal cord injury or multiple sclerosis and as much as 80% of the traumatic brain injury population. It can also be present in other conditions like amyotrophic lateral sclerosis, brain and spinal cord tumors, and cerebral palsy.

Symptoms

Patients may complain of increased tightness, worsening spasms, and pain when they come to the clinic, but more important, the main complaint can be worsening of functional activities. The ability to move affected limbs actively or passively is reduced. Spasticity significantly interferes with routine tasks and even hygiene (e.g., increased elbow flexor spasticity in a stroke survivor while walking; adductor spasticity in a paraplegic individual during urinary catheterization) while at the same time causing pain and muscle co-contraction. These symptoms may be due to a secondary condition that may increase spasticity, such as an infectious process, skin problems, and cord tethering. Thus, when a patient comes to the clinic complaining of worsening spasticity, a thorough history and physical examination should be performed to identify the cause.

Physical Examination

Spasticity occurs in the presence of other signs and symptoms of upper motor neuron damage. Other positive signs include hyperreflexia, Babinski responses, and clonus. Negative signs include muscle weakness, fatigue, reduced motor control, and loss of coordination. Increased muscle tone in the absence of these findings should lead to consideration of alternative causes of increased muscle tone, such as dystonia, Parkinson disease, or pain-associated muscle spasm. Strength testing may not be reliable as the spasticity may affect both range of motion because of contractures and co-contraction of antagonist muscles.

Muscle contracture as well as other soft tissue changes can be a part of this upper motor neuron syndrome, and it may be difficult in some cases to determine how much contracture is present in an individual with severe spasticity. A thorough physical examination can discover other issues associated with spasticity that could affect the individual, such as sensory disturbances (proprioception and spatial orientation), dysphagia, dysarthria, and skin issues. The skin should be inspected because abnormal positioning due to spasticity may directly cause skin injury (e.g., maceration of the palm due to a clenched fist) or contribute to pressure ulcer formation.

Sometimes it is important to differentiate spasticity from rigidity, commonly seen in conditions like Parkinson disease. One must look at some physical examination findings that occur with spasticity, such as the clasp-knife phenomenon.

There is also variability when antagonistic muscles are evaluated. In spasticity, for example, some muscle groups are more affected than their antagonist muscles. Rigidity is not velocity dependent; it is constant throughout the full range of motion.

Functional Limitations

Spasticity can cause significant functional limitations. In a patient with spinal cord injury, for example, spasticity can have a serious impact on positioning. It can affect wheelchair positioning as well as transfers. Hygiene and catheterization may be affected by significant hip adductor tone or spasticity. It will affect dexterity and fine motor coordination in the upper extremities. The use of bracing or other modalities to assist with ambulation may be limited if the spasticity is significant. Studies have found that a significant number of patients with both spinal cord injury and traumatic brain injury have noted that spasticity affects quality of life. In some cases, spasticity may serve as a partial substitute for voluntary muscle contraction. A common example of substitution for voluntary muscle function is the hip and knee extensor spasticity seen after stroke that may allow successful weight bearing through the weak leg and contribute to restoration of walking ability.

Diagnostic Studies

Spasticity is a clinical diagnosis, without any specific laboratory confirmation. Clinical measurement scales to quantify the severity of spasticity may be useful to monitor the efficacy of treatment. The most commonly used scales are the Ashworth scale (and a modified version of this scale) [1], which measures resistance of the muscle to passive stretch, and the Penn Spasm Frequency scale, which characterizes the frequency of muscle spasms [2] (Tables 153.1 and 153.2).

Table 153.1 Modified Ashworth Scale [1]

0	No increase in muscle tone
1	Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end range of motion when the part is moved in flexion or extension/abduction or adduction
1+	Slight increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the range of motion
2	More marked increase in muscle tone through most of the range of motion, but the affected part is easily moved
3	Considerable increase in muscle tone, passive movement is difficult
4	Affected part is rigid in flexion or extension (abduction or adduction)

Table 153.2 Penn Spasm Frequency Scale [2]

How often are muscle spasms occurring?	
0	No spasms
1	Spasms induced only by stimulation
2	Spasms occurring less than once per hour
3	Spasms occurring between 1 and 10 times per hour
4	Spasms occurring more than 10 times per hour

Differential Diagnosis

Dystonia
Rigidity (e.g., Parkinson disease)
Paratonia
Pain-associated muscle spasm
Contracture

Treatment

Initial

Management of spasticity should always be decided in the setting of functional and clinical scenarios. As noted before, spasticity can be used to the patient's advantage, such as ambulation in the setting of spastic hemiparesis. Treatment should be started when spasticity becomes an obstacle to functional goals as well as to safety (spasms while transferring that could lead to a fall), hygiene, and skin integrity management. A change in previously well controlled spasticity should always lead to consideration of possible irritants or nociceptive stimuli that might be "triggering" the spasticity. Examples are urinary tract infections, skin breakdown, occult fractures, and an ingrown toenail in an insensate limb (e.g., in a paraplegic person).

There are several options for oral medications (Table 153.3) that have had mixed results in the different diseases that cause spasticity. Spasticity caused by injury to the spinal cord tends to respond better to oral medications such as baclofen and tizanidine than does spasticity caused by a traumatic brain injury or a stroke. Some of the centrally acting medications, such as baclofen, tizanidine [3], and the benzodiazepines, have significant side effects that may impair cognition and overall recovery after an acquired brain injury [4]. Another commonly used drug is dantrolene [5], which works directly at the muscle level, preventing calcium flux at the sarcoplasmic reticulum and thereby reducing muscle force.

Rehabilitation

A physical management program of therapeutic exercise, stretching, and passive range of motion initiated by trained physical and occupational therapists is imperative for the management of spasticity, regardless of cause. Goals of therapeutic exercise are to maintain range of motion, to prevent contractures, to reduce muscle overactivity, and to disrupt maladaptive spasticity patterns. Active exercise can also increase muscle strength [6].

Stretching and passive range of motion serve to prevent contracture formation and temporarily reduce increased muscle tone, especially in patients who are not capable of active movement. Therapists can instruct the patient and caregivers in appropriate stretching techniques. Standing has been shown to be helpful in tone management as well as to have many other benefits. Physical modalities including ultrasound treatment have been used to facilitate stretching, although ultrasound had no effect in minimizing the spasticity at the gastrocnemius compared with passive stretching exercises in one trial [7]. The results of a different study did show that neuromuscular electrical stimulation with

Table 153.3 Commonly Used Oral Antispasticity Medications

Medication	Mechanism of Action	Starting Dose	Common Side Effects	Relative Contraindications
Baclofen	GABA _B agonist Increases presynaptic and postsynaptic inhibition	5-10 mg tid (maximum dose: 80 mg/day)	Sedation, rare hepatotoxicity, withdrawal symptoms	Cognitive impairment, seizures
Diazepam (benzodiazepines)	GABA _A agonist	2 mg tid	Sedation, respiratory ataxia	History of benzodiazepine or other substance abuse
Tizanidine	α ₂ -Agonist Suppresses polysynaptic reflexes	2 mg tid (maximum dose: 32 mg/day)	Sedation, hypotension, hepatotoxicity	Cognitive impairment
Dantrolene	Prevents calcium influx at the sarcoplasmic reticulum in the muscle	25 mg daily	Weakness, hepatotoxicity, occasional sedation	Liver disease

Table 153.4 Characteristics of Different Botulinum Toxins

	OnabotulinumtoxinA*	AbobotulinumtoxinA†	IncobotulinumtoxinA‡	RimabotulinumtoxinB§
Serotype	A	A	A	B
Packaging, units/vial	100 or 200	300 or 500	50 or 100	2500, 5000, or 10,000
Preparation	Vacuum dried	Lyophilized	Lyophilized	Solution (5000 units/mL)
Storage for packaged product	Refrigerator	Refrigerator	Room temperature, refrigerator, or freezer	Refrigerator
Storage after reconstitution	2° C-8° C for 24 hours	2° C-8° C for 4 hours	2° C-8° C for 24 hours	2° C-8° C for 4 hours

stretching of the wrist extensor muscles was more effective than stretching alone in reducing spasticity [8]. External cooling of a spastic limb may provide a temporary reduction in spasticity, but this modality is generally impractical as a long-term therapy.

Splinting is another imperative treatment in a comprehensive spasticity rehabilitation program. This can include prefabricated splints, low-temperature thermoplastic custom orthotics, and plaster or fiberglass casts. Serial casting has been shown to be effective both on its own and after botulinum toxin treatment in improving both passive range of motion and the modified Ashworth scale score [9].

Procedures

Treatment with injections is an effective means of obtaining substantial reduction in spasticity in specific muscles while minimizing the risks of systemic or sedating side effects. Prior to botulinum toxin, two compounds have been used for local muscle relaxation: local anesthetics (lidocaine, etidocaine, and bupivacaine) and alcohols (ethyl alcohol and phenol). Local anesthetic injections have a fully reversible action and are of short duration; therefore, they can be useful in assessing the efficacy and benefits of more permanent injections. Chemical neurolysis with phenol in concentrations of 5% to 7% and alcohol in concentrations of 45% to 100% have an advantage of lower cost, rapid onset of action, and potency but have risks of dysesthesias and muscle fibrosis and require more skill and time to perform [10].

Chemodenervation with botulinum toxin has become a mainstay of practice in the treatment of spasticity for graded relief in selected muscles. Intramuscular injection of botulinum toxin provides local relief of spasticity for 2 to 6 months. There are currently four toxins available: onabotulinumtoxinA, rimabotulinumtoxinB, abobotulinumtoxinA, and incobotulinumtoxinA. There is ample literature on and Food and Drug Administration approval of all four agents for the treatment of cervical dystonia. There are now more publications on the type A products that document their utility in the management of spasticity [11–14]. The American Academy of Neurology published an evidence-based position paper on spasticity in 2008 supporting the use of botulinum toxin as a treatment to decrease tone and to improve passive function. In addition, it should be considered to improve active function [15]. Furthermore, with all injection procedures, adjunctive treatments such as physical and occupational therapy will improve the delivery of therapy and improve the outcome [16]. The dosing and administration of botulinum toxins are not standardized and must be managed with great care as they are not clinically equivalent. Some differences in the four botulinum toxins are shown in Table 153.4.

Surgery

Several surgical interventions are used for spasticity. An important neurosurgical intervention is placement of an intrathecal baclofen pump into the abdominal wall. In this

system, there is an infusion of a prescribed rate of baclofen that is administered to the intrathecal space through a catheter system. This intervention has been found to reduce severe spasticity of cerebral and spinal origin, including in patients with cerebral palsy, spinal cord injury, brain injury, multiple sclerosis, and stroke. Evidence suggests that not only can intrathecal baclofen reduce spasticity, it can also improve function and quality of life [17] as well as improve gait in ambulatory patients [18,19].

Other neurosurgical techniques include stereotactic ablation or stimulation and cerebellar stimulation, which have been shown to have variable to uncertain results. Spinal cord surgeries such as selective posterior rhizotomy and myelotomy have been used as well in specially selected patients.

Neuro-orthopedic consultation can be obtained for further correction of limb deformities when conservative measures performed by a multidisciplinary team have been ineffective. Surgical procedures including tendon release or lengthening, tenotomy, and joint fusion can lead to improvement in functional outcome, pain, and subjective satisfaction [20,21].

Potential Disease Complications

Permanent loss of range of motion and contracture can result from inadequately controlled spasticity or insufficient stretching and splinting. Lost range of motion can also lead to difficulty with dressing, hygiene, and grooming activities. Skin issues can result, including accumulation of moisture, skin irritation, bacterial overgrowth, infection, and skin breakdown. Bone and joint issues, such as adhesive capsulitis, complex regional pain syndrome, and subluxation of joints, can occur.

Potential Treatment Complications

All of the centrally acting medications can cause significant sedation, which limits and therefore determines the dosage that can be tolerated. In individuals with preexisting cognitive impairments (e.g., stroke, traumatic brain injury), the sedative side effects can hinder rehabilitation goals, and the maximally tolerated dosage may be insufficient to control the symptoms of spasticity. Alternative treatments or use of the agents only before bedtime can be considered. Abrupt discontinuation of oral antispasticity medications is inadvisable. Seizures have been described after abrupt discontinuation of baclofen, and rebound spasticity is a concern with all of these medications.

In individuals with marginal motor function who may be relying in part on spasticity as a substitution for voluntary motor control, excessive reduction in spasticity may lead to reduced functional ability (e.g., loss of the ability to stand in a patient with paraparesis). Oral medication or intrathecal baclofen doses can generally be titrated to avoid this side effect; however, injected treatments (botulinum toxin, phenol) are more of a problem if overtreatment occurs.

Phenol carries some risk for painful dysesthesia, muscle fibrosis, scarring, and edema after injection. Botulinum toxin is generally well tolerated in therapeutic doses but does carry a Food and Drug Administration–mandated black box warning of a rare but potentially life-threatening

complication when the effects of the toxin spread far beyond the injection site, causing systemic weakness, vision changes, dysarthria, dysphonia, dysphagia, and respiratory insufficiency. This can be avoided by careful selection of muscles, proper method of injection guidance (e.g., electromyography, ultrasonography, or motor point electrical stimulation), appropriate dilution of toxin, and restriction of dosage to the minimal dose needed to obtain a therapeutic effect. Antibodies to botulinum toxin can develop after repeated injection, which can render treatment ineffective.

Intrathecal baclofen pump treatment can result in postdural puncture headache, iatrogenic meningitis, or infection of the external surface of the pump. Complications can also involve the medication (e.g., known adverse effects of baclofen are drowsiness and weakness) but are more frequently the result of malfunction of the intrathecal baclofen therapy system due to the pump, catheter, or human error. Interruption or underdosing of drug delivery can lead to a life-threatening withdrawal syndrome. Catheter failures can result in need for surgical intervention.

Definitions

A summary of the speech and language disorders described in this chapter is presented in [Table 154.1](#).

Aphasia is an acquired, neurogenic language processing impairment that can disrupt the modalities of language, including speaking, listening, reading, and writing. Aphasia is commonly caused by stroke; it occurs in 21% to 38% of cases of acute stroke and is associated with high morbidity, mortality, and financial cost [1]. However, aphasia can result from brain injuries other than stroke, such as tumors and head trauma, and it must be differentiated from motor

or sensory dysfunction, psychiatric illness, confusion, or general intellectual impairment [2]. In the United States, there are approximately 100,000 new cases of aphasia per year; the majority are women and 65 years of age or older [3]. Primary progressive aphasia is a term reserved for subtle, insidious progressive language impairments associated with frontal-temporal dementia. In primary progressive aphasia, there is relative preservation of other mental and cognitive functions for at least the first 2 years of the condition [4].

Aphasia is classified into subtypes according to the ability to produce, to understand, and to repeat language [5]. The ability to produce language is assessed in terms of fluency, defined as the rate of speech and the amount of effort in producing speech. Each subtype of aphasia is associated with a specific profile of language capabilities and disabilities ([Table 154.2](#)). For example, an individual with Wernicke aphasia produces fluent language, has impaired auditory comprehension, and has poor repetition skills. In contrast, Broca aphasia is characterized by nonfluent language, relatively intact auditory comprehension, and poor repetition skills.

Motor speech disorders, which include dysarthria and apraxia of speech, result from neurologic impairment affecting motor planning, neuromuscular control, or execution of speech [6]. Apraxia of speech results from a disruption in programming of the volitional movements for speech and is characterized by difficulty in orchestrating the movements of the lips, tongue, jaw, soft palate, vocal cords, and respiratory system for the production of speech. It can occur without muscle weakness or impairments in receptive and expressive language. Apraxia of speech is a distinct disorder, although some of its symptoms can co-occur in the presence of dysarthria and aphasia [7].

Dysarthria, a group of motor speech disorders resulting from damage to the central or the peripheral nervous system, affects 10% to 65% of individuals with acquired brain injury, depending on the type, extent, and duration of injury [8]. Dysarthria results from weakness, paralysis, or dyscoordination of the speech muscles that impairs articulation, respiration, resonance, and phonation (voice production). Dysarthria is divided into subtypes according to the speech characteristics and underlying pathophysiologic process. Neurogenic speech disorders should be differentiated from those resulting from structural problems (such as cleft palate or post-laryngectomy status) or psychogenic disorders [6].

Table 154.1 Speech and Language Disorders

Disorder	Definition
Aphasia	Language processing disturbance that can involve the expression of language, the comprehension of language, or both Word finding errors and difficulty in understanding language are classic indicators of aphasia.
Dysarthria	Group of motor speech disorders associated with muscle paralysis, weakness, or incoordination Dysarthria often is manifested as slurred speech and does <i>not</i> involve language (receptive or expressive) processes.
Apraxia of speech	Motor speech disorder disrupting the motor programming of the volitional movements for speech Individuals struggle to find correct position of articulators (i.e., lips, tongue). It can occur without muscle weakness or impairments in receptive and expressive language.
Dysphonia	Faulty or abnormal phonation (voice production) Vocal quality may sound hoarse, harsh, strained, or breathy.

The extreme form of dysarthria is anarthria, in which the individual is entirely incapable of producing articulated speech. Individuals with dysarthria often have dysphagia, or impaired swallowing, regardless of the etiology or duration [9]. This is readily understood, considering the overlap of structures and functions used in speaking and swallowing (see Chapter 129).

Dysphonia is faulty or abnormal phonation (voice production). Although prevalence rates are not well established, dysphonia is common in any condition causing abnormal motion of the vocal cords or dyscoordination of breathing and speaking. These include brainstem stroke, Parkinson disease, amyotrophic lateral sclerosis, Guillain-Barré syndrome, myasthenia gravis, spastic dysphonia, and multiple sclerosis, among others [6], as well as secondary processes that alter the structure or function of the vocal cords, including vocal abuse (such as excessive talking, screaming, or smoking), trauma (traumatic or prolonged intubation,

arytenoid dislocation), status post-laryngeal surgery, and a variety of disorders (laryngeal cancer, reflux laryngitis) [10]. Dysphonia is distinguished from dysarthria in that dysphonia involves only the sound of the voice, whereas dysarthria involves the overall sound of speech, including resonance and articulation.

Symptoms

Individuals with aphasia often complain of difficulty in speaking, reading, writing, or understanding speech. They often report difficulty in finding the word they wish to say and can become frustrated; however, some are unaware of their deficits. Individuals who solely have a motor speech disorder (e.g., dysarthria, dysphonia, or apraxia of speech) have no difficulty in finding the words they wish to say and report no difficulties with reading, writing, or auditory comprehension but complain primarily of difficulty in producing intelligible speech. Aphasia develops most commonly after left hemisphere stroke even in people who are left handed, whereas neglect, visual-spatial impairments, and other cognitive syndromes are more common after right hemisphere strokes [11].

Physical Examination

During the initial history and physical, the physiatrist should attend to speech intelligibility, vocal quality, language content, fluency, and auditory comprehension. Deficits in these areas warrant referral to a certified speech-language pathologist for comprehensive evaluation including standardized testing. In the rehabilitation setting, the Functional Independence Measure is widely used to measure functional abilities including communication [12]. Typical findings are described here for the four main categories of speech and language disorders.

Aphasia

Findings indicative of aphasia vary according to the location and size of the brain lesion (see Table 154.2). One classic sign of aphasia is difficulty in comprehending language

Table 154.2 Aphasia Syndromes

Aphasia Type	Predicted Lesion Site	Comprehension	Fluency	Repetition
Broca	Inferior frontal gyrus; Brodmann area	Relatively intact	Nonfluent	Poor
Wernicke	Posterior superior temporal gyrus; Brodmann area	Impaired	Fluent	Poor
Conduction	Superior marginal gyrus and underlying white matter (arcuate fasciculus)	Relatively intact	Fluent	Poor
Transcortical motor	Anterior and superior to Broca area (watershed area)	Relatively intact	Nonfluent	Good or less impaired than spontaneous speech
Transcortical sensory	Posterior and inferior to Wernicke area (watershed area)	Impaired	Fluent	Good
Transcortical mixed (isolation)	Anterior and posterior association areas (watershed areas)	Impaired	Nonfluent	Less impaired than spontaneous speech
Anomic	Angular gyrus or anywhere in left hemisphere	Relatively intact	Fluent	Good
Global	Left frontal, parietal, and temporal lobes	Impaired	Nonfluent	Poor

Modified from Helm-Estabrooks N, Albert ML. Manual of Aphasia and Aphasia Therapy, 2nd ed. Austin, Texas, Pro-Ed, 2004.

(spoken, gestural, or written). Significant impairment can be characterized by difficulty in following simple commands, whereas milder impairments may be obvious only during lengthy or complicated messages. Individuals who have aphasia may also have deficits in verbal expression (producing meaningful verbal output), which may be manifested as a total loss of language, with the production of only jargon (multiple whole-word substitutions) or meaningless sounds. A person with less severe aphasia may be able to express basic wants and needs but have difficulty in expressing complex ideas in conversation. Paraphasias, or naming errors, are a classic symptom of aphasia. Phonemic paraphasias involve the substitution, addition, or omission of target sounds (phonemes). For example, an individual may say “bable” for “table.” A semantic paraphasia occurs when an individual produces a word related in meaning to the target word (i.e., “fork” for “spoon”). The severity of impairment can vary for each modality of language (listening, reading, writing, recognition of numbers, and gesturing). Aphasia is *not* a result of decreased auditory or visual perceptual skills, disordered thought processes, impaired motor programming, or weakness or incoordination of speech musculature [1].

Apraxia of Speech

The most common sign of apraxia of speech is a struggle to speak. This struggle is a direct result of the difficulty in finding the correct position of the articulators (i.e., lips, tongue). Speech is often halting and may contain sound substitutions, distortions, omissions, additions, and repetitions [6]. The individual is aware of his or her speech errors and will attempt to correct them with varying degrees of success. Severe forms of apraxia of speech may result in the inability to produce simple words. Interestingly, most people with apraxia of speech can produce common everyday phrases or sayings (e.g., *How are you? Have a nice day. Thank you.*) without error. A symptom that commonly coincides with apraxia of speech is nonverbal oral apraxia, which is the inability to imitate or to follow commands to perform volitional movements with the mouth or tongue [6]. Apraxia of speech is not caused by muscle weakness, decreased tone, or incoordination, nor is it the result of linguistic disturbances as in aphasia. Sound-level errors in apraxia of speech are thought to result from difficulty with motor execution and not with the selection of phonemes found in aphasia [4]. Apraxia of speech differs from dysarthria in that apraxia of speech is not a result of paresis or paralysis or the uncoordinated movements of speech muscles. Rather, it is believed to reflect a disturbance in the programming of movements used for speech [7]. In contrast to dysarthric errors, which are typically consistent and predictable, errors in apraxia of speech are highly irregular.

Dysarthria

In dysarthria, speech is often characterized as being slurred; the predominant errors are distortions of speech sounds. Dysarthria may also be characterized by changes in a person's rate, volume, and rhythm of speech. The findings vary greatly, depending on the pathophysiologic mechanism. Table 154.3 presents an overview of dysarthria classification.

Table 154.3 Classification of Dysarthria

Type	Localization	Motor Deficit
Flaccid	Lower motor neuron	Weakness, hypotonia
Spastic	Bilateral upper motor neuron	Spasticity
Ataxia	Cerebellum	Incoordination; inaccurate range, timing, direction; slow rate
Hypokinetic	Extrapyramidal system (basal ganglia circuit)	Variable speed of repetitive movements, rigidity
Hyperkinetic	Extrapyramidal system	Involuntary movements
Mixed	Multiple motor systems (amyotrophic lateral sclerosis, multiple sclerosis)	Weakness, reduced rate and range of motion

Modified from Duffy JR. *Motor Speech Disorders: Substrates, Differential Diagnosis, and Management*, 2nd ed. St. Louis, Elsevier Mosby, 2005.

Dysphonia

Dysphonia is characterized by a reduction or alteration in voice quality. Vocal quality can vary by degrees of loudness, breathiness, hoarseness, or harshness. A common example of dysphonia is the hoarse vocal quality of individuals with laryngitis. In the extreme form, aphonia, the individual is incapable of producing any voice but may be able to produce voiceless speech (e.g., whispering).

Functional Limitations

Functional limitations depend on the nature and severity of the communication impairment. Severe deficits can impair the ability to express basic daily needs or to understand simple directions. The individual may not be able to effectively interact with family members or health care providers. Less severe deficits allow the individual to express and to understand basic information but impair high-level activities. These include the expression and understanding of complex and lengthy information to meet vocational or social needs. Speech and language impairments can affect an individual's ability to complete a range of daily life tasks, including the ability to read bills and newspapers or environmental signs, to communicate using the telephone, and to participate effectively in conversations or school or employment activities. Speech and language impairments may result in frustration and can cause disruptions in personal relationships, community and religious participation, and vocational functioning. Individuals with aphasia often participate in fewer activities and report worse quality of life even when physical limitations, well-being, and social support are comparable to those of other individuals [13].

Diagnostic Studies

The speech-language pathologist or neuropsychologist can administer a variety of standardized instruments to diagnose aphasia. The aim of these instruments is to identify

the pattern of symptoms to classify the aphasic syndrome, which is critical for the development of individualized interventions. Similarly, there are structured assessments for the diagnosis of dysarthria, dysphonia, and apraxia of speech. Performed by a speech-language pathologist, these in-depth assessments involve an oral-motor examination to identify the structure and function of oral, pharyngeal, and laryngeal musculature as well as speech characteristics (i.e., rate, volume, and intelligibility). For determination of the etiology and pathophysiology of dysphonia, a referral to an otolaryngologist is warranted. Laryngoscopy is often necessary to evaluate both the structure and the function of the larynx. Biopsy is indicated when a mass lesion is noted. Stroboscopic examination of the larynx, electroglottography, and acoustic voice analysis may reveal subtle abnormalities of vocal fold motion and resulting acoustic parameters [14,15]. The voice spectrogram is sometimes useful for quantitative assessment of vocal features.

Differential Diagnosis

APHASIA

Confusion, delirium, or dementia
Psychosis
Apraxia of speech
Dysarthria
Neurogenic stuttering
Echolalia
Palilalia
Selective mutism
Depression

APRAXIA OF SPEECH

Dysarthria
Aphasia
Neurogenic stuttering

DYSARTHRIA

Apraxia of speech
Aphasia
Depression
Abulia

DYSPHONIA

Acute and chronic laryngitis
Laryngeal hyperfunction (abuse and misuse)
Neurogenic disorders
Psychogenic disorders (i.e., conversion dysphonia)
Spasmodic dysphonia
Structural disorders of the larynx (congenital, traumatic, arthritic, neoplastic)

Treatment

Initial

Treatment of speech and language disorders usually requires referral to a speech-language pathologist. Initial treatment depends on the nature and severity of the disorder. The treatment plans for aphasia, apraxia of speech, dysarthria, and dysphonia vary greatly and must be individualized to meet each patient's communication needs. Initial intervention may include education of the patient and family

about the communication impairment and compensatory strategies to facilitate communication.

Rehabilitation

To maximize a patient's communication skills, a speech-language pathologist can offer specific strategies, exercises, and activities to regain functional communication abilities.

Aphasia

Aphasia rehabilitation is efficacious in the stroke population [16,17]. Intervention depends on the aphasia subtype and the individual's specific strengths and weaknesses. General models of aphasia therapy involve stimulating intact language processes, facilitating maximal language and speech processes through hierarchical cues and prompts, and compensating for refractory deficits through alternative communication systems and partner-facilitated communication strategies [18]. Common therapeutic activities may involve naming tasks that use hierarchical cueing techniques to improve language content and structure. Therapy may begin with the production of automatic speech tasks, such as stating numbers or the days of the week. More difficult tasks may involve individually naming objects and describing pictures using appropriate sentence and word forms. Errorless naming techniques and gestural training can promote recovery of word retrieval [19]. The training of scripts can allow the individual to produce rehearsed sentences to meet needs in specific situations [20]. Written expression can be targeted through functional activities such as writing and copying biographical information. Common activities to improve auditory comprehension include following simple or complex commands and answering spoken questions correctly. Therapy to improve reading comprehension may involve matching objects to written words, following written directions, or reading functional information (bills, medication labels, environmental signs). Activities that involve attention training, problem solving, and executive functioning skills were shown to have a positive effect on verbal expression and auditory comprehension [21,22]. Furthermore, collaboration between the speech-language pathologist and other skilled services, such as occupational therapy, can improve the patient's daily living skills.

Treatment for aphasia includes education. It is important to teach the individual with aphasia, family, and health care providers compensatory strategies to facilitate communication. Environmental modification and partner-facilitated approaches can dramatically improve communication success [23–25]. These can include turning off the television to reduce distractions, speaking slowly, using simple language, offering a pen and paper, checking that you are understood, and paraphrasing. Effective word-finding strategies include the use of circumlocutions, such as descriptions, definitions, or even sound effects during communication breakdowns. Training of volunteers to serve as conversation partners by the Supported Conversation for Adults with Aphasia intervention has been shown to be effective [26].

Advances in computer technology have provided therapists with new options in treating aphasia. Computer programs allow clinicians to easily design activities, to select stimulus items, to present cues, and to individualize reinforcements [27,28]. Software programs also can be used to

turn a computer into a speech output communication device, allowing people with severe aphasia to produce phrases and sentences of varying degrees of complexity [29–31]. These programs often contain features such as word prediction and graphic cues to facilitate correct sentence structure. Video technology has allowed individuals with aphasia to follow pre-recorded mouth movements with auditory and written cues to aid word retrieval for full sentences and even longer narratives [32,33]. The growing popularity of user-friendly smart phones has allowed individuals with aphasia and other speech disorders easy access to tools for enhancing communication including photos, videos, maps, pre-recorded messages, and text support.

Recent changes in reimbursement for aphasia therapy encouraged development of the Life Participation Approach to Aphasia. This philosophy focuses on long-term life goals, incorporating “aphasia-friendly” environments, use of communication partners, and identification of barriers to life participation [34].

Dysarthria

Rehabilitation for dysarthria also depends on the specific subtype. Approaches to treatment include medical intervention, oral prosthetic devices, and behavioral management [6]. For example, people with dysarthria due to Parkinson disease may benefit from dopamine agonists. Palatal lifts and voice amplifiers are commonly used to improve intelligibility. A palatal lift and augmentation prosthesis have been used successfully in conjunction with behavioral management [35]. Behavioral management of dysarthria involves muscle strengthening (e.g., lip closure, tongue protrusion, tongue elevation), improvement of breath support, and modification of posture. The person with dysarthria learns to use compensatory techniques to decrease rate of speech, to increase loudness, and to “overarticulate.” As with aphasia, the family is educated in strategies to maximize communication. Treatment of severe dysarthria or aphasia can include use of an augmentative communication system in which the individual uses pictures, written words, and alphabet or pictograph boards to enhance communication. Some individuals can use computer systems that produce synthesized speech. These offer a wide variety of communication topics and can be personalized to the individual’s needs.

Apraxia of Speech

Treatment of apraxia of speech involves techniques to elicit accurate voluntary speech production. The speech-language pathologist incorporates multimodality cues, such as modeling mouth and lip movements, using verbal cues to describe accurate tongue and lip placement, and intoning words and sentences. Treatment approaches often incorporate the use of rate and rhythm control strategies [4]. For severe cases, alternative communication strategies, such as writing, drawing, and communication books, are used to augment or to replace speech.

Dysphonia

Management of dysphonia is based on the underlying disorder and the pathophysiologic process [36]. Vocal hygiene education and proper voicing techniques can improve vocal quality for individuals with vocal nodules due to laryngeal

hyperfunction (vocal abuse). Techniques to enhance vocal fold approximation are useful in individuals with vocal cord motion impairments. Laryngitis due to gastroesophageal reflux disease is treated with a combination of voice therapy and vigorous antireflux regimen including proton pump inhibitors [37].

Procedures

Injection of a paralyzed vocal cord with Gelfoam or Teflon can increase its mass, bringing the medial edge of the cord closer to the midline. This facilitates contact with the mobile contralateral vocal cord, thereby improving phonation. This solution is usually only temporary; however, surgery is helpful in some cases. For cases of spasmodic dysphonia, an injection of botulinum toxin into the affected muscles can result in improved voice by correcting the abnormal motion of the vocal folds [38].

Surgery

Surgery is sometimes needed for treatment of voice disorders. Individuals with mass lesions of the larynx may need surgical excision. For individuals with unilateral vocal cord paralysis, a surgical procedure can bring the paralyzed cord closer to midline to achieve appropriate glottal closure. Implantation of a small device into the paralyzed hemilarynx, pushing the paralyzed cord toward the midline, can provide a lasting improvement in voice quality.

Structural lesions (e.g., cleft palate) or functional disorders (e.g., weakness of the palatal elevators) may cause inadequate seal of the velopharyngeal isthmus (the space between the soft palate and the pharyngeal walls). In either case, a surgical procedure to narrow the defect can sometimes provide improved speech quality.

Potential Disease Complications

Individuals with severe speech and language disorders may suffer extreme psychosocial consequences, including isolation, unemployment, depression [39], alienation, ostracism, and inability to fulfill essential family roles. Aphasia has been shown to be a risk factor for disability after stroke and plays a significant role in quality of life issues [40].

Potential Treatment Complications

Injection or surgical implant of the larynx may result in complications including infection, hemorrhage, and local tissue trauma. Injected material may gradually slip out of place and lose effectiveness, but this rarely leads to serious sequelae. Botulinum toxin injection rarely causes airway obstruction if the vocal folds become immobilized in the medial position. Leakage of the toxin into adjacent muscles may worsen the voice disorder or produce dysphagia.

G82.54 Quadriplegia, C5-C7 incomplete

Definition

Cervical spinal cord injury (SCI) results in tetraplegia. The term *tetraplegia* (preferred to quadriplegia) refers to an impairment or loss of motor or sensory function in the cervical segments of the spinal cord due to damage of neural elements within the spinal canal [1]. The result is impairment of function in the arms as well as in the trunk, legs, and pelvic organs. Impairment of sensorimotor involvement outside the spinal canal, such as brachial plexus lesions or injury to peripheral nerves, should not be referred to as tetraplegia.

In a complete cervical SCI, sensory or motor function is absent in the lowest sacral segments S4-S5 (i.e., no anal sensation or voluntary anal contraction is present). If sensory or motor function is partially preserved below the neurologic level and includes the lowest sacral segments, the injury is defined as incomplete [1,2]. The American Spinal Injury Association Impairment Scale (AIS) is used in grading the

degree of impairment (Table 155.1). Central cord syndrome is an incomplete SCI syndrome that applies almost exclusively to cervical SCI. It is characterized by greater weakness in the upper limbs than in the lower limbs and sacral sensory sparing [1].

SCI primarily affects young men. However, the average age at injury has increased from 28.7 years in the 1970s to 41.0 years since 2005, and the proportion of new SCI in adults older than 60 years has increased from 4.7% to 13.2% in the same time period in the national Spinal Cord Injury Model Systems database [3]. Males account for about 80% of injuries. The most common cause is motor vehicle accidents, followed by falls, violence (primarily gunshot wounds), and recreational sporting activities [2,3]. The proportion of injuries due to falls has increased over time. Cervical injuries occur more frequently than thoracic and lumbar injuries and accounted for 56.6% of the SCI database between 2005 and 2008. Since 2005, the most frequent neurologic category at discharge reported to the database is incomplete tetraplegia (40.8% of all SCI).

Symptoms

Primary symptoms of cervical SCI are related to muscle paralysis, sensory impairment, and autonomic impairment (including bladder, bowel, and sexual dysfunction). The patient can present in the outpatient setting with a multitude of secondary conditions [4] and associated problems. Symptoms may be vague and nonspecific. For example, urinary tract infections may be manifested not with classic symptoms of urgency and dysuria but with increased spasticity, increased frequency of spontaneous voiding, and lethargy [5]. The patient with pneumonia may present with fever, shortness of breath, or increasing anxiety. Headache may be indicative of autonomic dysreflexia and may be the primary or only presentation of a variety of pathologic processes ranging from bladder distention, urinary infection, constipation, or ingrown toenail to myocardial infarction or acute abdominal emergencies [6]. Table 155.2 lists common presenting symptoms of autonomic dysreflexia and underlying causes.

Because symptoms can reflect a variety of underlying conditions, these need to be evaluated carefully. For example, pain in cervical SCI may be multifactorial and needs to be further assessed by characteristics reported in the history, including quality, location, onset, timing, relieving and exacerbating factors, and associated

Table 155.1 American Spinal Injury Association Impairment Scale

Grade	Category	Description
A	Complete	No sensory or motor function is preserved in the sacral segments S4-S5.
B	Sensory incomplete	Sensory but no motor function is preserved below the neurologic level including the sacral segments S4-S5.
C	Motor incomplete*	Motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle grade less than 3.
D	Motor incomplete*	Motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a muscle grade 3 or more.
E	Normal	Sensory function and motor function are normal; the patient may have abnormalities in reflex examination.

*There must be some sparing of sensory or motor function in S4-S5 segments to be classified as motor incomplete.

Table 155.2 Etiology of Common Symptoms in Spinal Cord Injury

Symptom	Possible Cause
Fever	Infectious Urinary tract infection Pneumonia Infected pressure ulcer, cellulitis, osteomyelitis Intra-abdominal or pelvic infection Hot environment (due to poikilothermia) Deep venous thrombosis Heterotopic ossification Pathologic limb fracture
Fatigue	Drug fever (e.g., from antibiotics or anticonvulsant pain medications) Nonspecific, but could be the only symptom of serious illness Infection Respiratory or cardiac failure Side effect of medications
Daytime drowsiness	Depression (inquire about associated dysphoric symptoms) Side effect of medications (e.g., narcotics, antispasticity agents) Nocturnal sleep apnea Ventilatory failure with carbon dioxide retention
Shortness of breath	Depression Pneumonia Abdominal distention (e.g., postprandial, obstipation) Pulmonary embolus Ventilatory impairment (can be postural with sitting up if borderline) Cardiac causes
Diarrhea	Altered bowel management schedule <i>Clostridium difficile</i> infection Spurious diarrhea with bowel impaction Side effect of medications (antibiotic, excess laxative or stool softener)
Rectal bleeding	Hemorrhoids Trauma from bowel care
Hematuria	Colorectal cancer Urinary tract infection Urinary stones Traumatic bladder catheterization Bladder cancer
Headache	Autonomic dysreflexia; may be associated with any noxious stimulus below injury level Consider other causes in absence of increased blood pressure
Increased spasticity	Urine infection Pressure ulcer Bowel impaction Any noxious stimulus Syringomyelia
Pain	Multiple nociceptive and neuropathic causes (see Table 155.3)
Unilateral leg swelling	Osteoporotic fracture of the lower extremity Deep venous thrombosis Heterotopic ossification Cellulitis Hematoma Invasive pelvic cancer
New weakness or numbness	Syringomyelia Entrapment neuropathy (median at wrist, ulnar at elbow)

Table 155.3 International Spinal Cord Injury Pain Classification

Tier 1: Pain Type	Tier 2: Pain Subtype	Tier 3: Primary Pain Source or Pathologic Process
Nociceptive pain	Musculoskeletal pain Visceral pain	Example: glenohumeral arthritis, lateral epicondylitis, femur fracture Example: myocardial infarction, abdominal pain due to bowel impaction, cholecystitis
Neuropathic pain	Other nociceptive pain	Example: autonomic dysreflexia headache, migraine headache, surgical skin incision
	At-level SCI pain Below-level SCI pain Other neuropathic pain	Example: spinal cord compression, nerve root compression Example: spinal cord ischemia, spinal cord compression Example: carpal tunnel syndrome, trigeminal neuralgia, diabetic polyneuropathy
Other pain		Example: fibromyalgia, complex regional pain syndrome type I, irritable bowel syndrome
Unknown pain		

symptoms. Various SCI pain classification systems have been described. The International Spinal Cord Injury Pain classification (Table 155.3) organizes SCI pain into three tiers: tier 1 classifies pain type as nociceptive, neuropathic, other, and unknown; tier 2 includes various subtypes for neuropathic and nociceptive pain; and tier 3 is used to specify the primary pain source or pathologic process [7].

Physical Examination

The neurologic examination is conducted by systematic examination of the dermatomes and myotomes (Tables 155.4 and 155.5) in accordance with the *International Standards for Neurological and Functional Classification of Spinal Cord Injury*, published by the American Spinal Injury Association [1]. Depending on the presentation, specific elements of the physical examination of various body systems that are relevant in evaluation of SCI-related conditions may include the following.

Neurologic

- Determine the level and completeness of the injury (Fig. 155.1). Conduct the examination in the supine position.
 - Sensory examination for pinprick and light touch sensation in key points bilaterally (see Table 155.4)
 - Motor examination for strength in key muscle groups bilaterally (see Table 155.5)
 - Neurologic rectal examination (voluntary anal contraction, deep anal sensation)
- Determine completeness of injury and AIS grade (see Table 155.1). If the AIS grade is A, determine the zone of partial preservation.
- Additional elements of the neurologic examination include
 - Position and deep pressure sensation, testing of additional muscles
 - Muscle tone and spasticity
 - Muscle stretch reflexes, bulbocavernosus reflex, plantar reflex

Respiratory

- Assess respiratory effort, including effect of posture (e.g., sitting versus supine).
- Check for paradoxical respiration and chest expansion.
- Auscultate to assess for decreased breath sounds, rales, and wheeze.

Table 155.4 Key Sensory Points for Cervical Spinal Segments

Level	Key Sensory Point
C2	Occipital protuberance
C3	Supraclavicular fossa
C4	Top of the acromioclavicular joint
C5	Lateral side of the antecubital fossa
C6	Thumb, dorsal surface, proximal phalanx
C7	Middle finger, dorsal surface, proximal phalanx
C8	Little finger, dorsal surface, proximal phalanx
T1	Medial side of antecubital fossa

Table 155.5 Key Muscle Groups for Cervical Myotomes*

Level	Muscle Group	Positions for Testing Key Muscles for Grades 4 and 5
C5	Elbow flexors (biceps, brachialis)	Elbow flexed at 90°, arm at patient's side, forearm supinated
C6	Wrist extensors (extensor carpi radialis longus and brevis)	Wrist in full extension
C7	Elbow extensors (triceps)	Shoulder in neutral rotation, adducted, and in 90° of flexion, with elbow in 45° of flexion
C8	Finger flexors (flexor digitorum profundus) to the middle finger	Full-flexed position of the distal phalanx with the proximal finger joints stabilized in extended position
T1	Small finger abductors (abductor digiti minimi)	Full-abducted position of the fifth digit of the hand

*For those myotomes that are not clinically testable by manual muscle examination (e.g., C1 to C4), the motor level is presumed to be the same as the sensory level.

Cardiac

- Low baseline blood pressure is often a “normal” finding in SCI.
- Look for orthostatic symptoms or excess fall in blood pressure with sitting or upright position.

- High blood pressure may indicate autonomic dysreflexia ([Table 155.6](#)).
- Examination of peripheral pulses may be especially important for identification of peripheral vascular disease in the absence of claudication and pain symptoms.

- Examine for abdominal distention; examine bowel sounds for evidence of ileus.
- Perform anorectal examination for hemorrhoids and fissures.

- Identify spinal deformity and tenderness.
- Observe spinal precautions if the examination is being conducted in the acute or postoperative state.

- Examine for range of motion, contractures, and swelling.
- Identify nociceptive sources of pain; palpate for tenderness.
- Differentiate effects of SCI (pedal edema, cool extremities) from additional pathologic processes.

- Examine bone prominences for erythema or skin breakdown.

- Sudden, significant increase in blood pressure
- Pounding headache
- Flushing of the skin above the level of the SCI, or possibly below
- Blurred vision, appearance of spots in the patient's visual fields
- Nasal congestion
- Profuse sweating above the level of the SCI, or possibly below the level
- Piloerection or goose bumps above the level of the SCI, or possibly below
- Bradycardia (may be a relative slowing only and still within normal range)
- Cardiac arrhythmias
- Feelings of apprehension or anxiety
- Minimal or no symptoms, despite a significantly elevated blood pressure

- Describe any pressure ulcers: location, appearance, size, stage, exudate, odor, necrosis, undermining, sinus tracks; evidence of healing in form of granulation and epithelialization; wound margins and surrounding tissues [8].

Functional Limitations

Tetraplegia is associated with several functional limitations based on the level and completeness of injury [9]. Additional factors, such as age, comorbid conditions, pain, spasticity, body habitus, and psychosocial and environmental factors, can affect function after cervical SCI. A survey of individuals with tetraplegia conducted to rank seven functions in order of importance to their quality of life revealed that the greatest percentage ranked recovery of arm and hand function as their highest priority [10] (Table 155.7).

The Consortium for Spinal Cord Medicine has developed clinical practice guidelines on outcomes after SCI

Table 155.7 Functional Recovery Priorities of Persons with Cervical Spinal Cord Injury

Area of Functional Recovery	Percentage Surveyed Ranking as the Most Important Item
Arm and hand function	48.7
Sexual function	13.0
Trunk stability	11.5
Bladder and bowel	8.9
Walking movement	7.8
Normal sensation	6.1
Chronic pain	4.0

From Anderson KD. Targeting recovery: priorities of the spinal cord-injured population. *J Neurotrauma* 2004;21:1371-1383.

with expected functional outcomes for each level of injury in a number of domains [9,11]. Expected functional outcomes and equipment needs for each level of complete cervical SCI are summarized in Tables 155.8 and 155.9.

Table 155.8 Pattern of Weakness and Functional Outcomes after Cervical Spinal Cord Injury*

Domain	C1-C4	C5	C6	C7-C8
Pattern of upper extremity weakness	Total paralysis of extremities	Absent elbow extension and pronation, all wrist and hand movements	Absent wrist flexion, elbow extension, and hand movement	Limited grasp release and hand dexterity due to intrinsic muscle weakness
Respiratory	Ventilator dependent (some C3, many C4 may be able to be weaned off ventilator)	Low endurance and vital capacity; may require assistance to clear secretions	Low endurance and vital capacity; may require assistance to clear secretions	Low endurance and vital capacity; may require assistance to clear secretions
Bowel management	Total assist	Total assist	Some to total assist	Some to total assist
Bladder management	Total assist	Total assist	Some to total assist with equipment; may be independent with leg bag emptying	Independent to some assist
Bed mobility	Total assist	Some assist	Some assist	Independent to some assist
Bed and wheelchair transfers	Total assist	Total assist	Level transfer: some assist to independent Uneven transfer: some to total assist	Level transfer: independent Uneven transfer: independent to some assist
Pressure relief/positioning	Total assist; may be independent with equipment	Independent with equipment	Independent with equipment or adapted techniques	Independent
Wheelchair propulsion	Manual: total assist Power: independent with equipment	Power: independent Manual: independent to some assist indoors on non-carpet surface; some to total assist outdoors	Power: independent with standard arm drive on all surfaces Manual: independent indoors; some assist outdoors	Manual: independent on all indoor surfaces and level outdoor terrain; may need some assist or power for uneven terrain or long distances
Eating	Total assist	Total assist for setup, then independent eating with equipment	Independent with or without equipment, except total assist for cutting	Independent
Dressing	Total assist	Some assist for upper extremities; total assist for lower extremities	Independent upper extremities; some to total assist for lower extremities	Independent upper extremities; independent to some assist for lower extremities
Homemaking	Total assist	Total assist	Some assist with light meal preparation; total assist for other homemaking	Independent for light meal preparation and homemaking; some assist with heavy household tasks
Driving	Total assist, attendant-operated van (with lift, tie-downs)	Independent with highly specialized modified van	Independent driving a modified van from wheelchair	Car with hand controls or adapted van from captain's seat

*These outcomes pertain to expected function after motor complete SCI; functional outcomes after incomplete SCI vary on the basis of the extent of motor preservation.

Table 155.9 Equipment Needs after Cervical Spinal Cord Injury

Equipment Category	C1-C4	C5	C6	C7-C8
Respiratory	Ventilator (if not ventilator free) and suction equipment			
Bed	Electric hospital bed, pressure relief mattress	Electric hospital bed, pressure relief mattress	Electric hospital bed or full to king size standard bed, pressure relief mattress or overlay	Electric hospital bed or full to king size standard bed, pressure relief mattress or overlay
Transfers	Power or mechanical lift, transfer board	Power or mechanical lift, transfer board	Mechanical lift, transfer board	Transfer board may be needed
Wheelchair	Power wheelchair with tilt or recline (with postural support and head control devices as needed), vent tray, pressure relief cushion	Power wheelchair with tilt or recline with arm drive control, manual lightweight chair with hand rim modifications, pressure relief cushion	Lightweight manual wheelchair with hand rim modifications, may require power recline or standard upright power wheelchair, pressure relief cushion	Lightweight manual wheelchair with hand rim modifications, pressure relief cushion
Bathing and toileting	Reclining padded shower-commode chair (if roll-in shower available), shampoo tray, hand-held shower	Padded shower-commode chair or padded transfer tub bench with commode cutout, hand-held shower	Padded transfer tub bench with commode cutout or padded shower-commode chair, hand-held shower	Padded transfer tub bench with commode cutout or padded shower-commode chair, hand-held shower
Eating, dressing, and grooming	Total assist; specialized equipment, such as a balanced forearm orthosis, may allow limited feeding ability in those with C4 SCI and minimal (<3/5) strength in deltoid and biceps	Long opponens splint (with pocket for inserting utensils), long-handled mirror, adaptive devices as needed	Short opponens splint, universal cuff, long-handled mirror, adaptive devices as needed	Adaptive devices as needed, long-handled mirror
Communication	Mouthstick, high-tech computer access, environmental control unit	Adaptive devices as needed (e.g., for page turning, writing, button pushing, computer access)	Adaptive devices as needed (e.g., tenodesis splint, writing splint)	Adaptive devices as needed
Transportation	Attendant-operated van (with lift, tie-downs)	Highly specialized modified van with lift	Modified van with lift, tie-downs, hand controls	Modified vehicle

Diagnostic Studies

Spinal Imaging

Radiologic studies are performed to identify and to characterize the site of the pathologic change. Magnetic resonance imaging is especially helpful because of its ability to visualize the soft tissues, including ligamentous structures, intravertebral discs, epidural or subdural hematomas, and hemorrhage or edema in the spinal cord. Magnetic resonance imaging with gadolinium is helpful in diagnosis of post-traumatic syringomyelia.

Electrodiagnostic Testing

Electromyography and nerve conduction studies may be helpful in distinguishing lesions of the peripheral nerves or brachial plexus from those of the spinal cord when patients present with neurologic worsening [12].

Urologic Studies

Urodynamic studies assess neurogenic bladder and sphincter dysfunction. Tests to evaluate upper urinary tracts may be indicated on a periodic basis, but there currently is no

uniform consensus on the type or frequency of these tests [4]. Periodic cystoscopy may be indicated in those with chronic indwelling urinary catheters because of increased risk of bladder cancer [13].

Pulmonary Function

Patients who are at high risk for pulmonary complications, such as those with high tetraplegia or with concomitant chronic obstructive airway disease, may require yearly measurements of forced vital capacity and repeated evaluations when new symptoms arise [14]. Chest radiographs will show evidence of pneumonia or atelectasis. Sputum culture and Gram stain will identify the involved pathogens and help guide antibiotic therapy.

Musculoskeletal Imaging

Radiographic evaluation may be needed in case of suspected fracture or to evaluate pain. Heterotopic ossification may be assessed with a bone scan in addition to plain radiographs [12]. If a pressure ulcer appears to involve the bone, magnetic resonance imaging or bone scan may be helpful to evaluate for osteomyelitis [5].

Differential Diagnosis

Cervical spinal stenosis with myelopathy
 Spinal infections, abscess
 Primary or metastatic tumors
 Brainstem disease
 Motor neuron disease
 Lesions of the brachial plexus
 Disorders involving multiple nerves (e.g., polyneuropathy, Guillain-Barré syndrome)

Treatment

Initial

Initial management includes adequate spinal immobilization and prevention of secondary injury. Physiatric consultation and intervention in an acute setting should address range of motion, positioning, bowel and bladder management programs, clearance of respiratory secretions, ventilatory management, consideration of venous thromboembolic prophylaxis, prevention of pressure ulcers, input about functional implications of options for surgery and spinal orthosis, and education of the patient and family [15].

Rehabilitation

Information about potential for motor recovery can be used to set functional goals and to plan for equipment needs (as described in [Tables 155.8](#) and [155.9](#)), keeping in mind that individual factors and coexisting conditions may affect achievable goals [9]. Important elements of rehabilitation include an interdisciplinary approach, establishment of an individualized rehabilitation program with consideration of unique barriers and facilitators, and inclusion of the patient as an active participant in establishment of goals [11]. Specialized equipment needs, based on the level of injury, are summarized in [Table 155.9](#).

In addition to the post-acute rehabilitation that follows the injury, lifelong rehabilitation interventions are often indicated to address changes in neurologic status, new goals, changes in living situation, functional decline associated with medical complications and comorbidities, and aging [16]. Home modifications should be instituted to ensure accessibility [11].

Ongoing Management and Health Maintenance

There is general consensus that comprehensive preventive health evaluations for individuals with SCI are important [4], although uniform agreement about optimal frequency and specific elements is lacking. Because all body systems are potentially affected by cervical SCI, long-term management needs to be comprehensive as summarized here.

Respiratory

Respiratory infections should be promptly identified and treated [17]. Measures such as smoking cessation and pneumonia and annual influenza vaccinations are important for reducing respiratory problems [4]. Manually assisted cough methods can be taught to patients and caregivers. It is important to recognize and to address worsening

ventilatory function that may occur with aging or after other complications.

Cardiovascular

Autonomic dysreflexia is a life-threatening emergency, and persons with tetraplegia can be at lifelong risk. Prompt identification and management are critical. The Consortium for Spinal Cord Medicine has published clinical practice guidelines for the acute management of autonomic dysreflexia [6]. If the patient has signs and symptoms of dysreflexia (see [Table 155.6](#)), the blood pressure is elevated, and the individual is supine, immediately sit the person up. Loosen any clothing or constrictive devices. Monitor the blood pressure and pulse frequently. Quickly survey for instigating causes, beginning with the urinary system. If an indwelling urinary catheter is not in place, catheterize the individual. Before the catheter is inserted, instill lidocaine jelly (if it is readily available) into the urethra. If the individual has an indwelling urinary catheter, check the system along its entire length for kinks, folds, constrictions, or obstructions and for correct placement of the indwelling catheter. If a problem is found, correct it immediately. Avoid manual compression of or tapping on the bladder. If the catheter is not draining and the blood pressure remains elevated, remove and replace the catheter. If the catheter cannot be replaced, consult a urologist. If acute symptoms of autonomic dysreflexia persist, including a sustained elevated blood pressure, suspect fecal impaction. If the elevated blood pressure is at or above 150 mm Hg systolic, consider pharmacologic management to reduce the systolic blood pressure without causing hypotension before checking for fecal impaction. Use an antihypertensive agent with rapid onset and short duration (e.g., nifedipine bite and swallow, 2% nitroglycerin ointment, or prazosin) while the causes of autonomic dysreflexia are being investigated, and monitor the individual for symptomatic hypotension. If fecal impaction is suspected, check the rectum for stool. If the precipitating cause of autonomic dysreflexia is not yet determined, check for other less frequent causes. Monitor the individual's symptoms and blood pressure for at least 2 hours after resolution of the autonomic dysreflexia episode to make sure that it does not recur. If there is poor response to the treatment specified or if the cause of the dysreflexia has not been identified, strongly consider admitting the individual to the hospital to be monitored, to maintain pharmacologic control of the blood pressure, and to investigate other causes of the dysreflexia. Document the episode in the individual's medical record. Once the individual with SCI has been stabilized, review the precipitating causes with the individual and caregivers and provide education as necessary [6]. Individuals with tetraplegia and their caregivers should be able to recognize and to treat autonomic dysreflexia and be taught to seek emergency treatment if it is not promptly resolved.

Treatment of symptomatic orthostatic hypotension [11] addresses any exacerbating causes (e.g., medications, dehydration, or sepsis). Nonpharmacologic measures include postural challenges, abdominal binder, compression stockings, and increased salt intake. Pharmacologic treatment is administered if it is needed (e.g., with ephedrine, fludrocortisone, or midodrine).

Primary and secondary prevention of cardiovascular disease includes smoking cessation, diet and weight control, lipid management, screening for and treatment of hypertension and glucose intolerance or diabetes, and

individualized exercise program [18]. For evaluation of coronary artery disease, a modified or pharmacologic stress test is often needed in these individuals, and if a cardiac rehabilitation program is required, it can be adapted for wheelchair users.

Genitourinary

The goals of bladder management (Table 155.10) are to ensure low pressure and complete voiding, to minimize urinary tract complications, to preserve upper urinary tracts, and to be compatible with the individual's lifestyle [13]. Anticholinergic medications (e.g., oxybutynin, tolterodine) may be indicated for detrusor hyperreflexia and α -adrenergic blockers (prazosin, terazosin, tamsulosin) for detrusor-sphincter dyssynergia. Urinary infections should be identified and treated promptly, but antibiotics are generally not recommended for asymptomatic bacteriuria [5]. There is little role for prophylactic antibiotics, except before urologic procedures.

Counseling and education are key elements of managing sexual dysfunction [19]. Phosphodiesterase type 5 inhibitors (sildenafil, tadalafil, vardenafil) may be used to treat erectile impairment, although care needs to be taken to avoid simultaneous use of nitrate-based medications to treat autonomic dysreflexia, which could result in severe hypotension [4]. Other options include intracavernosal injections, devices, and implants. Advances in electroejaculation and fertility care have increased the fertility success rate for men with SCI. Female fertility is not affected once menses return, which typically occurs within 1 year of

injury. Pregnancy and delivery in women with SCI carries risks, including autonomic dysreflexia, and close follow-up is recommended [4,19].

Gastrointestinal

The goals of bowel management are to facilitate predictable and effective elimination and to minimize bowel incontinence [20]. A scheduled individualized bowel program should be established, which typically includes reflex stimulation maneuvers, laxatives (stool softeners, stimulants), dietary interventions, and adequate fiber intake. Laxatives and enemas should be kept to a minimum. One should beware of fecal impaction presenting as spurious diarrhea and pay due attention to new bowel symptoms.

Skin

Education of the patient, regular pressure relief practices, and prescription of pressure-reducing support surfaces are vital for prevention of pressure ulcers [8]. Daily comprehensive skin inspections should be carried out by the patient or caregiver, with particular attention to vulnerable insensate areas (e.g., sacrum-coccyx, ischii, trochanters, and heels). Adequate nutritional intake is important. Management of pressure ulcers is discussed further in Chapter 148.

Neurologic

If spasticity is painful or continues to interfere with function after institution of a stretching and positioning program and treatment of any exacerbating factors, medications are often indicated [21]. Table 155.11 lists commonly used medications. Chapter 153 provides additional discussion about spasticity. Selective tightening (e.g., wrist extensors for tenodesis or back extensors for sitting balance) may be important for function in tetraplegia. Neurologic worsening (e.g., due to focal neuropathy, syringomyelia) should be investigated and addressed appropriately [12].

Musculoskeletal

Measures for upper extremity preservation after SCI should be instituted early and followed lifelong. These include optimization of equipment and wheelchair to minimize upper extremity stresses, activity modification to minimize repetitive or excessive upper extremity forces during daily activities and transfers, and individualized exercise program incorporating appropriate flexibility and strengthening components [22].

It is important to recognize and to address contributing factors to pain, which is often multifactorial [7] (see Table 155.3). Pain medications (see Table 155.11) often do not provide complete or optimal relief [21].

Heterotopic ossification is treated with etidronate sodium, nonsteroidals, and occasionally surgical resection, especially if it is interfering with function or comfort [11]. Pathologic fractures should be recognized and treated with padded splints or bivalved circular casts, monitoring of skin integrity, and often only a limited role for surgical treatment [12]. The role for pharmacologic treatment of osteoporosis in SCI is still evolving. Fall prevention (education, wheelchair lap belts) is important to prevent injuries.

Table 155.10 Nonsurgical Options for Management of the Neurogenic Bladder in Spinal Cord Injury

Bladder Management	Indications
Intermittent catheterization	Often the first choice, if feasible Need sufficient hand skills or willing caregiver Must be willing and able to follow catheterization time schedule
Indwelling catheterization (urethral or suprapubic)	Consider for poor hand skills and lack of caregiver assistance Not able or willing to follow intermittent catheterization schedule High fluid intake Lack of success with less invasive measures Temporary management of vesicoureteral reflux Choose suprapubic with epididymo-orchitis, prostatitis
Credé and Valsalva Reflex voiding	Generally avoided in cervical SCI (unless the patient had sphincterotomy) Hand skills or willing caregiver to put on condom catheter, empty leg bag Confirmed small postvoid residual volumes, low voiding pressure Able to maintain condom catheter in place Need to also decrease detrusor-sphincter dyssynergia, if present (e.g., with alpha blocker, botulinum toxin injection, stent, sphincterotomy) Not an option for female patients

Table 155.11 Medications Commonly Used for Spasticity and Pain in Spinal Cord Injury*

Problem	Drug Class	Medication
Spasticity	GABA related	Baclofen Gabapentin
	α_2 -Agonist	Tizanidine Clonidine
	Benzodiazepine	Diazepam Clonazepam
	Calcium release inhibitor	Dantrolene
	Local injection	Botulinum toxin Phenol, alcohol
	Intrathecal agents	Baclofen
	Nonopioid analgesic	Acetaminophen Tramadol
Pain	Nonsteroidal anti-inflammatory drugs, salicylates	Nonsteroidal anti-inflammatory drugs, salicylates
		Morphine sulfate
		Oxycodone
	Opioid	Hydrocodone
		Fentanyl (transdermal)
		Gabapentin, pregabalin
	Anticonvulsant	Carbamazepine
		Other (phenytoin, valproic acid, lamotrigine)
		Amitriptyline
	Tricyclic antidepressant	Nortriptyline
	Local anesthetic cream	Lidocaine patch
	Neuroblocking	Capsaicin
	Intrathecal agents	Morphine, clonidine

*The list is not meant to be exhaustive but includes examples of commonly used medications.

Psychosocial

It is important to address environmental barriers (physical and attitudinal), to promote self-efficacy, and to optimize participation and community integration in response to changes in the living situation and social support, functional decline, and aging. Depression should be identified and treated adequately, and substance abuse prevention and treatment programs should be offered [23].

Procedures

Pressure Ulcers

Sharp débridement of pressure ulcers may be done at the bedside to remove necrotic tissue, although if it is extensive, débridement may need to be done in the operating room.

Spasticity

Motor point or nerve blocks with phenol or alcohol may be helpful in treating localized spasticity that interferes with positioning, mobility, or hygiene. Intramuscular injections of botulinum toxin are another option.

Pain

Shoulder pain due to subacromial bursitis may be temporarily responsive to local corticosteroid injections, as is the discomfort from carpal tunnel syndrome [22].

Surgery

Spine Surgery

When cervical spine injury is accompanied by mechanical instability, pain, deformity, or progressive neural impairment, surgical decompression and segmental instrumentation may be indicated for reconstruction of spinal alignment, stability, and early mobilization [12,15].

Pressure Ulcers

Plastic surgery may be indicated for deep pressure ulcers. This includes excision of the ulcer and surrounding scar and muscle and musculocutaneous flap closure [22].

Spasticity

If spasticity is not controlled with maximum dosages of oral medications, or if a patient is unable to tolerate the medications, the placement of an intrathecal baclofen pump may be considered.

Motor Function

Reconstructive surgery of the upper extremity with tendon transfers may improve motor function by one level, typically in those with a neurologic level at C5, C6, or C7. Depending on the level of injury, restoration of wrist extension, elbow extension, and key grip strength or improvement of active grasp and hand control may be an appropriate goal [24].

Functional electrical stimulation has been used in SCI to improve motor function, including upper limb control, standing, and walking, as well as for electrophrenic respiration for ventilator-free breathing [11].

Bladder Dysfunction

Surgical treatment of urolithiasis includes cystoscopic removal of bladder stones, lithotripsy, and percutaneous nephrolithotomy for larger renal stones. Endourethral stents or transurethral sphincterotomy may be considered in individuals with detrusor-sphincter dyssynergia [13]. Electrical stimulation and posterior sacral rhizotomy may be considered for individuals who have problems with catheterization, have good bladder contractions, have no extensive bladder fibrosis, and are willing to lose reflex erections [13]. Bladder augmentation may be indicated for intractable bladder contractions with incontinence and in those at high risk for upper tract deterioration. Urinary diversion may be an appropriate option for unsalvageable bladders secondary to urethral fistula and in individuals with bladder cancer requiring cystectomy [13].

Bowel Dysfunction

Patients with neurogenic bowel who have significant difficulty or complications with typical bowel care may have improved quality of life after colostomy. Careful selection of patients and individualization are required in consideration of this surgery [20].

Upper Extremity Pain

Surgery may occasionally be considered for chronic upper extremity overuse-related symptoms that are unresponsive to medical and rehabilitative treatment (e.g., for carpal

tunnel syndrome or rotator cuff disease). Outcomes are often poor if upper extremity overuse continues [22].

Post-traumatic Syringomyelia

Surgical placement of shunts may be indicated for post-traumatic syringomyelia associated with intractable pain or progressive neurologic decline.

Potential Disease Complications

Cervical SCI is associated with multiple complications that can involve every body system.

Respiratory

Respiratory problems include atelectasis, mucous plugs, and pneumonia secondary to impaired cough and retention of secretions; ventilatory failure with high tetraplegia; and sleep disordered breathing [17].

Cardiovascular

Patients with cervical SCI are prone to multiple cardiovascular complications throughout life [18]. Autonomic dysreflexia may occur in SCI above the T6 neurologic level and can be precipitated in response to any noxious stimulus below the level of injury. Symptomatic orthostatic hypotension often resolves after the first few months but may be persistent in some cases. Although venous thromboembolism risk is reduced after the initial months, it can increase even in chronic SCI in the setting of prolonged immobilization associated with medical illness or in the postsurgical state. Cardiovascular fitness is reduced and cardiovascular risk factors can be adversely affected (e.g., reduced high-density lipoprotein cholesterol, increased body fat and insulin resistance, decreased physical activity). Diagnosis of cardiovascular disease may be delayed because of confusing or absent symptoms and signs [18].

Genitourinary

Neurogenic bladder is associated with loss of voluntary control, detrusor-sphincter dyssynergia, and incomplete bladder emptying. Complications include urinary tract infection, bladder and kidney stones, vesicoureteral reflux, and hydronephrosis with renal impairment. Bladder cancer risk is increased with chronic indwelling catheter, especially in smokers [13]. Erectile and ejaculatory dysfunction occurs, and sperm quality may be impaired [4,19].

Gastrointestinal

There is loss of voluntary bowel control, anorectal dyssynergia, and reduced rectal expulsive force [20]. Fecal impaction may occur. Anorectal problems include hemorrhoids, fissures, proctitis, and prolapse. Gallstone risk is increased. Gastroesophageal reflux is common. False-positive results of examination for fecal occult blood may complicate colorectal cancer screening.

Skin

Pressure ulcers are common and may increase with duration of injury. Previous occurrence of a pressure ulcer is an important predictor of future pressure ulcers [8].

Metabolic and Endocrine

Hyponatremia may be a persistent problem in some patients. Carbohydrate and lipid metabolism is affected, and there may be glucose intolerance associated with relative insulin resistance [16]. A reduction in bone mineral density with secondary osteoporosis is common in chronic SCI and affects both the upper and lower extremities in those with tetraplegia.

Neurologic

Neuropathic pain can be persistent and have a negative impact on quality of life. Entrapment neuropathies (median nerve at wrist, ulnar nerve at elbow) and post-traumatic syringomyelia can result in neurologic deterioration [12].

Musculoskeletal

Overuse syndromes include shoulder pain and rotator cuff problems [12,22]. Contractures may occur without due attention to range of motion and positioning. Individuals with C5 level of injury are especially prone to elbow flexion and forearm supination contractures because of unopposed biceps activity. Heterotopic ossification, which is the development of ectopic bone within the soft tissues surrounding peripheral joints, occurs in SCI most commonly around the hip, followed by the knees, elbows, and shoulders [12]. It is further discussed in Chapter 130. Pathologic fractures may occur even with trivial injury because of severe osteoporosis [12].

Psychosocial

SCI can increase the potential for stress, isolation, and depression [23]. Alcohol and substance abuse risk seems to be increased.

Potential Treatment Complications

Spinal pain at the surgical site may result from loosening, infection, or broken hardware. Instability or neurologic deterioration may be due to inadequate spinal immobilization. Surgical shunts can become blocked or infected, and intrathecal pumps or catheters may malfunction.

Complications of urethral catheterization include urethral trauma, erosions, strictures, urinary infections, and epididymitis [13]. Chronic indwelling catheters increase the risk of stones and squamous cell carcinoma of the bladder. Complications may occur with surgical procedures for SCI-related problems, such as neurogenic bladder. For example, transurethral sphincterectomy may be associated with significant intraoperative and perioperative bleeding and erectile and ejaculatory dysfunction. Posterior sacral rhizotomy done in conjunction with electrical stimulation of the bladder may result in loss of reflex erection and ejaculation and reduction of reflex defecation. Urinary diversion procedures may be followed by intestinal or urinary leak, infection, ureteroileal stricture, stomal stenosis, and intestinal obstruction due to adhesions [13].

Because people with SCI are often prescribed multiple medications, drug-related side effects and complications are common. Cervical SCI can result in altered pharmacokinetics [25] in multiple ways (Table 155.12), which further increases unpredictability of side effects.

Table 155.12 Pharmacokinetic Changes in Spinal Cord Injury

SCI-Related Change	Impact on Pharmacokinetics
Delayed gastric emptying	Rapid absorption of acidic drugs
Reduced gastrointestinal motility	Delayed absorption of basic drugs
	Increased absorption of drugs that undergo enterohepatic circulation
	Decreased bioavailability of drugs that are destroyed by gut bacteria
Reduced blood flow to skin and muscle	Less reliable transcutaneous, subcutaneous, and intramuscular drug absorption below injury level
Increased percentage of body fat	Effect on fat- and water-soluble drug distribution
Reduced plasma protein level	Increased free fraction of protein-bound drugs
Impaired kidney function	Reduced renal elimination of drugs

ICD-10 Codes

G82.20 Paraplegia of both lower limbs, unspecified

G82.21 Paraplegia of both lower limbs, complete

G82.22 Paraplegia of both lower limbs, incomplete

Definition

Spinal cord injury (SCI) is a common cause of paralysis, particularly in young men (Table 156.1). Just more than one third of all injuries to the spinal cord occur at the thoracic level, most commonly at T12 [1]. With thoracic SCI, 68% of patients will have complete injury, 8% will have a sensory incomplete injury, and 23% will have a motor incomplete injury. Mean age at the time of injury has increased over time: from 2005 to 2011, the mean age was 41 years, compared with 28.7 years from 1973 to 1979. Overall, there is still higher representation of males with SCI, with 80.6% of patients being male and 19.6% being female [1]. Compromise to the thoracic spinal cord typically results in paraplegia. Unlike paraplegia that results from compromise of the cauda equina associated with lumbar spine injuries, the clinical findings are consistent with upper motor neuron injury. However, lower limb paralysis is not the only impairment. The thoracic spinal cord also segmentally innervates the intercostal muscles as well as the upper and lower

abdominal muscles. The intercostal muscles are innervated by the T1 to T12 spinal segments. The upper abdominal muscles are innervated by the T8 to T10 spinal segments; the T11 to T12 spinal segments innervate the lower abdominal muscles [2].

A quantitative three-dimensional anatomy of the thoracic spine reveals three distinct zones: the cervical-thoracic transition zone, the middle region, and the thoracic-lumbar transition zone [3,4]. The T1-T4 region is characterized by a narrowing of the vertebral end plate and spinal canal widths [3]. The middle thoracic region (T4-T9) is notable for its relatively narrow end plate and small spinal canal. The rib articulations provide an increased degree of protection at this level. An enlargement of the spinal canal characterizes the lower thoracic region (T10-T12) [3]. There is also less rigidity of the spine at the T11 and T12 segments because of the lack of ventral attachment of the ribs [3]. Therefore there is an increased vulnerability to SCI at the lower thoracic levels. Compared with the cervical and lumbar spinal levels, the blood supply is more tenuous in the thoracic spinal cord, and therefore ischemia poses a greater threat to neurologic function in this area [4].

Symptoms

The presenting symptoms of thoracic SCI are consistent with the alteration to the motor, sensory, and autonomic pathways. The chief symptoms are weakness or paralysis of the abdominal and lower extremity musculature and loss of sensation in the lower limbs, thorax, and perineum. Patients may also experience altered bowel or bladder function in addition to spasticity and sexual dysfunction.

With lesions above the T6 level, patients may experience the symptoms of autonomic dysreflexia. Autonomic dysreflexia is characterized by pounding headaches, nasal congestion, anxiety, visual disturbances, pallor below the level of injury, and sweating and flushing above the level of injury. In patients with an old, stable injury who are experiencing new or progressive symptoms (e.g., increasing weakness, loss of sensation), the clinician should consider the possibility of a syrinx.

Patients with SCI are often insensate to the pain that accompanies deep venous thrombosis, and therefore both the

clinician and the patient should be attentive to clinical signs such as edema, erythema, and increased tone. Heterotopic ossification may mimic deep venous thrombosis because the symptoms include swelling, decreased range of motion, erythema, increased spasticity, pain, and low-grade fever.

Pain originating from either musculoskeletal or neurologic sources is common. Neuropathic pain resulting from central or peripheral nervous disruption may be described as burning or shooting. An analysis of several studies addressing prevalence of pain after SCI showed a variable overall prevalence of pain ranging from as low as 26% to as high as 96% [5].

Physical Examination

The diagnosis of a thoracic-level SCI necessitates a thorough physical examination, including a comprehensive neurologic assessment. Findings on physical examination include a motor and sensory level. Depending on whether the injury is partial or complete, there may be sparing of sacral sensation or anal sphincter motor function below the neurologic level of injury. In the acute period, the motor examination is characterized by loss of muscle tone and deep tendon reflexes. During subsequent days and weeks, there is emergence of increased muscle tone, reflexes, and pathologic reflexes. Cutaneous reflexes including the plantar response, cremasteric reflex, and bulbocavernosus reflex are initially depressed and follow a variable course to gradual return. The initial evaluation of the patient also includes the assessment of vital signs and the cardiovascular, respiratory, musculoskeletal, gastrointestinal, and genitourinary systems. A thorough examination of the skin is necessary. In thoracic SCI, pressure ulcers are more common over bony prominences such as the sacrum, calcaneus, and greater trochanter. In addition, it is important to evaluate the patient for spasticity and contractures.

New neurologic abnormalities on physical examination should alert the clinician to consider imaging studies to exclude syringomyelia. In this case, typical physical examination findings include change in sensory level, change in motor level, and reflex abnormality as well as spasticity.

Functional Limitations

Persons who suffer from thoracic SCI can have significantly different levels of disability, depending on their degree of paralysis and associated potential complications (e.g., contractures, spasticity). A patient with high thoracic paraplegia (i.e., T2 level) typically has some component of truncal instability; as a result, the patient's wheelchair requires a high back. In contrast, a person with low thoracic paraplegia generally has preservation of most of the intercostal and abdominal muscles and could opt for a chair with a low back. Intercostal muscle impairment in patients with SCI in the upper thoracic region may cause an impaired cough and a decreased ability to mobilize secretions.

Functional goals for individuals with thoracic SCI include the ability to complete activities of daily living and instrumental activities of daily living with or without the use of assistive equipment. Tasiemski and colleagues [6] have described a positive association of involvement in sports and recreational activities with increased life satisfaction in a community sample of people with SCI. Numerous sports and recreational organizations offer adaptive sports programs for people with disabilities.

Bowel and bladder function may cause social embarrassment, leading to self-imposed social isolation. Sexual dysfunction may result in a loss of intimacy. The availability of partners is a concern for many patients because their disability as well as environmental and social barriers may preclude their involvement in some of the more typical dating activities.

Depression is common in patients with SCI; reported rates of depression in the newly injured range between 20% and 44% [7]. The most recent large-scale retrospective study of veterans with SCI showed a depression rate of 22% [8]. Depression has been associated with an increase in secondary complications and poor compliance with self-care activities [7]. Referral to mental health professionals is encouraged for patients at risk.

Diagnostic Studies

The diagnosis of thoracic SCI is often corroborated with magnetic resonance imaging. The stability of the injury is assessed by evaluation of the anterior, middle, and posterior columns of the spine. Magnetic resonance imaging is also the study of choice when syringomyelia is suspected.

Urodynamic testing is commonly used to evaluate bladder function in the individual with SCI. Urodynamic studies involve filling of the bladder with fluid or gas and use of electromyographic and fluoroscopic techniques to evaluate voiding function. Annual evaluations often include an ultrasound examination to further assess the integrity of the renal system.

Patients with grade IV pressure ulcers may require a bone scan or magnetic resonance imaging study to detect osteomyelitis. The triple-phase bone scan is also used in

the diagnosis of heterotopic ossification (see Chapter 130). Doppler surveillance studies are sometimes performed to detect deep venous thrombosis in this highly susceptible population (see Chapter 127). Routine colonoscopy and fecal occult blood testing may be appropriate for patients 50 years and older [9]. In patients susceptible to autonomic dysreflexia, appropriate precautions must be used during colonoscopy.

Differential Diagnosis

Amyotrophic lateral sclerosis
Post-traumatic syringomyelia
Guillain-Barré syndrome
Spinal cord infarction
Ischemic injury to spinal cord (i.e., secondary to abdominal and thoracic aneurysms)
Multiple sclerosis
Transverse myelitis

Treatment

Initial

Skin Management

In an analysis of long-term medical complications among subjects enrolled in the National Spinal Cord Injury Statistical Center database, pressure ulcers were the most commonly reported postinjury complication. McKinley and colleagues [10] reported a 15.2% incidence of pressure ulcers in the first annual follow-up postinjury year. The rates increased steadily during all follow-up years in both complete and incomplete SCIs. Common sites for pressure ulcers are the sacrum, greater trochanter, and heels. Excessive pressure, shearing, friction, and maceration can increase the risk for pressure ulcers. Other risk factors include spasticity, impaired sensation, immobility, poor nutrition, weight gain, and incontinence [11].

The maintenance of skin integrity is an ever-present goal in patients with SCI. Pressure ulcer formation will lead to the development of scar tissue and an even greater likelihood of ulcer recurrence. Seating surfaces should be reevaluated on a regular basis, ensuring that they have not worn out and still fit the patient's weight and size. Patients are encouraged to perform daily skin examinations, and most paraplegic patients are able to independently perform pressure-relieving strategies, such as wheelchair pushups. These techniques should be performed every 15 minutes to minimize excessive pressure.

Patients who have a pressure ulcer must minimize pressure to that area until the wound is healed. A variety of débridement methods are available for removal of necrotic debris from pressure ulcers (see Chapter 148).

Pain

The presentation of pain among the SCI population can be varied in nature; both neuropathic pain and pain resulting from abnormal mechanical stresses (e.g., tendinitis) are common. Many times, patients with musculoskeletal pain have a well-defined disorder that is amenable to standard physiatric treatment (e.g., rotator cuff tendinitis, lateral epicondylitis). Non-narcotic analgesics and nonsteroidal anti-inflammatory

drugs can be used to treat musculoskeletal causes of pain. Neuropathic pain generally is not responsive to these medications; however, tricyclic antidepressants, antiseizure medications, and pregabalin have been effective in its treatment but should be prescribed with caution [12].

Bladder Management

Most patients with thoracic-level SCI will have upper motor neuron bladder dysfunction, characterized by low urinary volumes, high bladder pressures, bladder trabeculation, and diminished bladder compliance. Detrusor-sphincter dyssynergia (co-contraction of the bladder and sphincter) is common. This can contribute to vesicoureteral reflux, which may result in hydronephrosis and subsequent chronic renal failure. Detrusor-sphincter dyssynergia can be treated with medical interventions that decrease bladder tone (e.g., oxybutynin) or, alternatively, decrease sphincter tone (e.g., terazosin, tamsulosin, or sphincter chemodenervation) [13,14] (see Chapter 137).

Bladder management strategies should be individualized, but intermittent catheterization is the preferred treatment option. A typical intermittent catheterization program requires bladder emptying four to six times per day, with volumes remaining less than 500mL. Most paraplegic patients have the manual dexterity to perform self-catheterization; some individuals, because of biologic or sociomedical factors, must use indwelling catheters (with suprapubic preferred to urethral). Indwelling catheters are associated with a higher incidence of bladder stones and bladder carcinoma [15]. In addition, in men, urethral catheters are associated with prostatitis, epididymitis, and urethral strictures. Long-term use of urethral catheters in women may result in urethral dilation.

Bowel Management

The patient with thoracic-level injuries will most likely have constipation; therefore a bowel program is necessary. A reasonable goal for a bowel regimen is to achieve socially acceptable fecal continence, with bowel evacuations at least three times per week. A bowel regimen may include medications (Table 156.2). In addition, bowel evacuation is scheduled after a meal to capitalize on the intrinsic increase in peristalsis after meals (i.e., the gastrocolic reflex). Bowel care programs done on a raised toilet seat use the benefits of gravity. Digital stimulation (gentle insertion of the finger) of the rectum or insertion of a suppository can activate the rectocolic reflex by stimulating peristalsis and promoting regular bowel movements. Enemas (Fleet, soapsuds) should not be part of a regular bowel program. However, these agents are useful in emptying the colon before initiation of a bowel program or treatment of fecal obstipation [9]. The administration of an enema can precipitate autonomic dysreflexia in susceptible patients. If administration of an oral osmotic laxative is required, consideration should be given to polyethylene glycol 3350 (PEG 3350) over the traditional use of lactulose. This is supported by a recent Cochrane review that demonstrated greater efficacy and less abdominal pain compared with lactulose for all-cause chronic constipation [16] (see Chapter 138).

Mental Health

Psychosocial adaptation subsequent to SCI is a lifelong process. There is no single "classic" presentation of this

Table 156.2 Oral Adjunctive Bowel Medications [9,16]

Medication	Brand	Mechanism of Action	Strength	Dose
Docusate sodium	Colace	Stool softener	100 mg (capsules)	1 tablet bid
Senna	Senokot	Colonic stimulant	8.6 mg (tablets)	1-2 tablets qhs
Bisacodyl	Dulcolax	Colonic irritant	5 mg (tablets)	2 tablets qd
Polyethylene glycol (PEG 3350)	Lax-A-Day, MiraLax	Osmotic laxative	17 g (powder)	17 g daily (dissolved in liquid)
Psyllium powder	Smooth Texture Sugar-Free Unflavored Metamucil	Bulk-forming agent	5.4 g per tsp	1 tsp qd-tid
Metoclopramide	Reglan	Prokinetic agent	10 mg (tablets)	1 tablet qid

Modified from Bergman S. Bowel Management. In Nesathurai S, ed. *The Rehabilitation of People with Spinal Cord Injury*, 3rd ed. Arbutle Academic Publishers, 2013.

phenomenon. Anger, hostility, anxiety, and depression often result from overwhelming losses confronting this population. Suicide is among the leading causes of death in these patients. In individuals with depression or other psychological sequelae, consultation with an appropriate mental health care professional is recommended. Continued follow-up is encouraged, when appropriate.

Sexual and Reproductive Function

Sexual desire is not necessarily affected by SCI. However, associated depression, fears of inadequacy, and poor body image may consequently alter sexual desire. Sexual function (e.g., erection and ejaculation in men and lubrication in women) in patients with thoracic-level injuries may be altered. In general, patients with more complete lesions have more impairment. Men with thoracic-level lesions (with intact sacral reflexes) generally can achieve reflex erections with direct genital stimulation. However, many times, these reflex erections are of insufficient rigidity and duration for satisfactory vaginal penetration [17].

Many patients with SCI have numerous questions and fears about sexuality and sexual function. Treatment should address concerns related to body image, dating, and initiation and maintenance of intimate relationships. Peer counselors can share their experiences, and their advice can be beneficial. Peer counselors may be located through local independent living centers or through advocacy organizations such as the National Spinal Cord Injury Association or Canadian Paraplegia Association. In addition, mental health professionals (e.g., psychologists, psychiatrists, social workers) can be a valuable resource to the patient and rehabilitation team.

Several options available to men with erectile dysfunction include oral medications (e.g., sildenafil [18–24], tadalafil [18,24–26], vardenafil [24]), vacuum devices, penile injection programs (papaverine) [27], and surgically implanted prostheses. Ejaculatory dysfunction is also common, including retrograde ejaculation into the bladder [28]. Chronic SCI is also associated with poor semen quality and decreased spermatogenesis [29]. Elevated scrotal temperatures (from chronic sitting) and frequent urinary tract infections may negatively affect semen quality. Although studies have indicated that approximately 12% to 15% of men with SCI report ejaculation, fatherhood has become a possibility with use of semen retrieval methods such as penile vibration and electroejaculation along with improved assisted reproductive technology [30]. The risk of autonomic

dysreflexia exists among susceptible patients with an injury level of T6 and above; therefore, assisted semen retrieval should be initiated by medical teams well trained in semen retrieval methods and the treatment of autonomic dysreflexia [31].

Women with thoracic-level lesions may note changes in vaginal lubrication. However, at this level, women may achieve reflex lubrication [32]. Direct stimulation of the genital region may result in sufficient lubrication. A water-soluble lubricant is recommended for patients with complaints of decreased vaginal lubrication. One randomized placebo-controlled study on the use of sildenafil to enhance sexual arousal in women with SCI failed to show a statistically significant benefit [33], despite an earlier pilot study that appeared to show benefit [34].

Orgasm for both men and women after injury may be nonexistent or described as a primarily emotional event or a pleasurable sensation in the pelvic region or sensory level with generalized muscle relaxation [32].

Women with thoracic-level SCI remain fertile. Contraceptive options include barrier methods (condoms, diaphragm) and oral contraceptives. Intrauterine contraceptive devices are contraindicated because of the lack of sensation and the risk for development of pelvic inflammatory disease. Patients with SCI are at increased risk for the development of thromboembolism, and the administration of oral contraceptives further increases this risk and should be discussed.

The care of pregnant women with SCI has special challenges. Potential complications include premature labor, increased risk of urinary tract infection, increased spasticity, autonomic dysreflexia, and constipation. In pregnancy, autonomic dysreflexia is manifested most frequently during labor; therefore hemodynamic monitoring is considered for all at-risk patients [35].

Pregnant women with thoracic SCI levels above T10 may be unable to sense fetal movements and contractions. Therefore, uterine palpation, serial cervical examinations, and fetal monitoring may be recommended. Regional anesthesia is preferred [36].

Deep Venous Thrombosis

SCI predisposes individuals to both deep venous thrombosis and pulmonary embolism. A systematic literature review revealed the prevalence of deep venous thrombosis in SCI to vary from 9% to 100% [37]. Of these, it is estimated that only 20% will extend into proximal veins, with associated

elevated risk of pulmonary embolism. The rate of pulmonary embolism has been found to be 8% to 14% in acute SCI, with rates of fatal pulmonary embolism as high as 5% [37]. Putative mechanisms include immobility as a result of paralysis and failure of the venous-muscle pump as well as the possible contribution of a generalized hypercoagulable state.

Patients are administered fractionated or unfractionated heparin during the initial weeks after injury and may use thigh-high compression stockings and pneumatic compression. Current literature suggests continuation for 8 to 12 weeks after injury. For more details on the prevention and treatment of deep venous thrombosis, see Chapter 127.

Spasticity Management

Spasticity should be treated when it results in significant pain, contributes to contractures, impairs hygiene, interferes with functional tasks, or impedes nursing care. In the first instance, clinically significant spasticity should be treated by removal of noxious stimuli that may be contributing to the condition, such as urinary tract infection, ingrown toenails, and tight clothing. Second, physical interventions such as daily stretching of muscles with terminal sustained stretch can be considered. If these are unsuccessful, medications such as tizanidine and baclofen as well as interventional procedures (e.g., chemodenervation) can be considered (see Chapter 153 for details).

Heterotopic Ossification

Heterotopic ossification is most often seen in the first 6 months after injury in the spinal cord-injured population, especially in the first 2 months [38,39]. The incidence of heterotopic ossification among individuals with SCI ranges from 10% to 53% [39]. It is estimated that 20% to 30% of those with heterotopic ossification will experience a significant loss of joint mobility [38]. Treatment may include the administration of etidronate, which limits ossification, and physical therapy to maintain range of motion (see Chapter 130).

Osteoporosis

Osteoporosis among patients with SCI is common. Immobilization and the lack of weight-loading activities are among the chief causes of osteoporosis. Other factors may include alterations in blood circulation, lack of muscle traction on bone, and hormonal changes [40]. The loss of bone density develops in the acute stage of injury, with demineralization occurring below the level of injury [41]. Patients with SCI are at significant risk for long bone fracture, and care must be taken to prevent fractures resulting from range of motion exercises and falls. There is evidence from several studies that bisphosphonates may slow or stop the loss of bone density after SCI, but guidelines as to their use have not yet been developed [40]. In the absence of clear guidelines, investigation, treatment, and monitoring for osteoporosis in SCI patients remains somewhat empirical. Supplementation with vitamin D is often recommended, although calcium supplementation remains controversial because of the associated risk of urinary calculi [12] (see Chapter 140 for further details).

Autonomic Dysreflexia

For the treatment of autonomic dysreflexia, it is necessary to remove the precipitating noxious stimulus. Patients

should be placed in an upright position, if possible, to decrease blood pressure, and a search for a causative agent is initiated. Most cases of autonomic dysreflexia are related to bladder distention or bowel distention [42]. However, noxious stimuli such as ingrown toenails, pressure ulcer, and renal calculi are not uncommon. Vasodilating medications such as nitropaste may be required to decrease the blood pressure while the clinician seeks the causative factor [43]. Nitrates are contraindicated in individuals who have ingested cyclic guanosine monophosphate-specific phosphodiesterase type 5 inhibitors, such as sildenafil, as the nitrates can potentiate the hypotensive effects of sildenafil and cause severe hypotension [37].

Rehabilitation

A comprehensive rehabilitation program is essential to optimize functional independence. The program should address functional goals related to mobility, transfers, and self-care as well as issues related to health maintenance and self-advocacy. Depending on the outstanding treatment goals, the treatment team may include a physical therapist, occupational therapist, orthotist, nurse, and mental health provider.

Mobility is a major issue that needs to be addressed both initially and then periodically as the patient's condition changes (e.g., women who become pregnant may require assistance with functional activities as the pregnancy progresses). Typically, patients with thoracic SCI are able to achieve mobility with a manual wheelchair. Higher levels of thoracic SCI are associated with greater truncal instability. This may affect stability in a wheelchair and should be addressed with the seating prescription. Most patients with thoracic injuries, with training, are able to transfer independently.

For assistance with independence in self-care, adaptive equipment, such as long-handled shoehorns and reachers, can be recommended. Home environmental modifications may also be necessary (i.e., ramp to enter home). Patients with thoracic SCI should be able to drive a modified car or van.

Passive interventions, such as therapeutic heat and cold as well as transcutaneous electrical nerve stimulation, may be beneficial in the management of pain. However, particular caution must be used with therapeutic heat or cold modalities over insensate areas.

As well, with higher levels of injury, there is increasing loss of intercostal muscle innervation and increased level of respiratory impairment. Techniques including incentive spirometry, manual assisted cough, and insufflation-exsufflation can be used to reduce pulmonary complications of thoracic SCI.

Physical interventions, such as daily stretching of muscles with terminal sustained stretch, can be considered a first-line rehabilitative treatment for spasticity. Positioning as well as serial casting and splinting of the affected limbs can minimize spasticity.

Other rehabilitation treatments may also be considered. Functional electrical stimulation may improve muscle strength, decrease muscle atrophy, and improve lower limb endurance [44]. Body weight-supported treadmill training is prescribed in many centers. This intervention has been

shown to be as effective as traditional gait training practices in the first year after injury with regard to functional outcomes [44]. The use of lower limb bracing may be an option in individuals with thoracic SCI, predominantly in those with lower thoracic level.

Procedures

A number of procedures can be used to address issues such as spasticity and pain. Interventional approaches for the treatment of spasticity include botulinum toxin injection, motor branch blocks, and peripheral nerve blocks (see Chapter 153). To decrease sphincter tone in men, botulinum toxin can be injected into the sphincter. This treatment in women is associated with an unacceptably high incidence of urinary incontinence. A patient with dysreflexia caused by a bladder stone may require a urologic procedure for stone removal. For men with ejaculatory dysfunction, retrieval of sperm for insemination has been successfully accomplished by electroejaculation and vibrostimulation methods. These procedures may result in dysreflexia and are performed under medical supervision.

Surgery

Pressure ulcers that do not heal with conservative methods may require surgical closure. Direct closure, skin grafts, musculocutaneous flaps, and skin flaps are among the surgical treatments available for wound closure. Mobilization after surgical closure must be done under close supervision, with careful monitoring of the surgical wound.

A variety of surgical procedures are used in patients who cannot be satisfactorily maintained with an intermittent catheterization program. Sphincter tone can be reduced with a sphincterotomy for men. Men must wear external collection devices after this procedure because it results in continuous incontinence. Sphincterotomies may occasionally require revision because of the development of fibrosis that obstructs outflow. Sphincterotomies may result in erectile dysfunction in some men. In contemporary practice, sphincterotomies are performed less frequently.

Bladder augmentation is occasionally performed to increase bladder capacity. A piece of small bowel is interposed with the bladder tissue to increase vesical volume. Patients with chronic dysreflexia resulting from persistent bowel management difficulties, such as frequent impaction, may be candidates for ileostomy or colostomy procedures. Patients with hemorrhoids aggravated by digital stimulation occasionally require surgical consultation if the hemorrhoids are not relieved by more conservative methods (e.g., medicated suppositories or topical steroid creams).

On occasion, men with erectile dysfunction that is not amenable to less invasive therapies may opt for an implantable penile prosthesis. Again, with the introduction of medications to treat erectile dysfunction, these surgeries are less frequently performed. Surgical placement of an intrathecal morphine or baclofen pump may be beneficial for patients with severe pain or spasticity that is not responsive to noninvasive treatments. Surgical interventions are indicated in some cases of heterotopic ossification. Patients with functionally limited joint mobility or severe

and chronic spasticity may benefit from surgical resection of the lesion.

Potential Disease Complications

Individuals with thoracic-level SCI are more likely to have associated injuries that are serious than are those with cervical or lumbosacral spinal cord lesions. In one study, patients with traumatic thoracic spine fractures had an 86.2% occurrence of additional traumatic injury, such as rib fractures (42.1%), pulmonary contusions (37.5%), pneumothorax or hemothorax (34.9%), cervical spine injury (31%), lumbar spine injuries (28.4%), clavicular fractures (11.9%), sternal fractures (10.7%), and scapular fractures (10.3%) [45]. Thoracic SCI may be associated with a lower life expectancy. The leading causes of death among people with SCI in the national Spinal Cord Injury Model Systems database are respiratory, infectious, and cardiovascular diseases [1]. Complications arising from a thoracic-level injury result from immobility, changing sensory patterns, and alterations in autonomic nervous system function.

Potential Treatment Complications

The anticholinergic side effects of tricyclic antidepressants, including dry mouth, blurred vision, and urinary retention, can pose additional difficulties for the patient with SCI. Sphincterotomies, performed to alleviate detrusor-sphincter dyssynergia, may result in urinary incontinence and occasionally sexual dysfunction in men. Voiding by the Credé maneuver may lead to vesicoureteral reflux. The long-term use of indwelling catheters is associated with prostatitis, epididymitis, strictures, bladder stones, and bladder carcinoma.

Digital stimulation of the bowel can result in autonomic dysreflexia and hemorrhoids.

Medications used to treat autonomic dysreflexia can result in hypotension. The blood pressure must be closely monitored.

When the less invasive methods of treating spasticity are ineffective, more interventional approaches to spasticity, including chemodenervation with botulinum toxin or neurolysis with phenol injections, motor branch blocks, peripheral nerve blocks, and intrathecal baclofen pump insertion, may be considered. Injections may result in bleeding or infection. Nerve blocks may result in dysesthesias and weakness. Patients with intrathecal baclofen pumps may experience drowsiness, weakness, catheter breakage, or infection.

Spinal Cord Injury (Lumbosacral)

Sunil Sabharwal, MD

Synonyms

Paraplegia
Conus medullaris syndrome
Cauda equina syndrome

ICD-9 Codes

344.1 Paraplegia
344.6 Cauda equina syndrome
344.9 Paralysis, unspecified
806.4 Fracture of the vertebral column with spinal cord injury: lumbar
806.6 Fracture of the vertebral column with spinal cord injury: sacral

ICD-10 Codes

G82.20 Paraplegia, unspecified
G82.21 Paraplegia, complete
G82.22 Paraplegia, incomplete
G83.4 Cauda equina syndrome
G83.9 Paralytic syndrome, unspecified
S32.009 Unspecified fracture of unspecified lumbar vertebra
S34.109 Unspecified injury to unspecified level of lumbar spinal cord
S32.10 Unspecified fracture of sacrum
S34.139 Unspecified injury to sacral spinal cord
Add seventh character for S32 (A—initial encounter for closed fracture, B—initial encounter for open fracture, D—subsequent encounter for fracture with routine healing, G—subsequent encounter for fracture with delayed healing, K—subsequent encounter for fracture with nonunion, P—subsequent encounter for fracture with malunion, S—sequela)
Add seventh character for episode of care for S34

Definition

Lumbosacral spinal cord injury (SCI) refers to impairment or loss of motor or sensory function in the lumbar or sacral segments of the spinal cord, secondary to damage of neural elements within the spinal canal [1]. With this level of injury, arm and trunk functions are spared, but the legs and pelvic organs are involved.

The terms *lumbosacral* SCI and *paraplegia* are also used in referring to conus medullaris and cauda equina injuries but not to impaired sensorimotor function due to neural involvement outside the spinal canal (as in lumbosacral plexus lesions or injury to peripheral nerves). Conus medullaris syndrome results from an injury to the sacral spinal cord (conus) and lumbar nerve roots within the spinal canal. Cauda equina syndrome refers to injury to the lumbosacral nerve roots within the neural canal.

Lumbosacral injuries account for about 11% of SCI cases in the national Spinal Cord Injury Model Systems database [2]. The most common causes of injury include motor vehicle crashes, falls, acts of violence, and recreational sporting activities [3,4]. There is an association between level of injury and cause of injury, and acts of violence are more often associated with paraplegia than with cervical injury and tetraplegia [2].

Neurologic versus Skeletal Level of Injury

Lumbosacral SCI refers to the neurologic level of injury, which is different from the skeletal level of injury. Because of the discrepancy between the lengths of the spinal cord and the vertebral column, the L1-L5 lumbar spinal cord segments are typically located at the T11-T12 vertebral level, and the S1-S5 sacral spinal cord segments are at the L1 vertebral level. The spinal cord ends between T12 and L2 (most often at L1 vertebra), and injury within the neural canal below that bone level involves the cauda equina. Lesions at the level of the lowermost thoracic and first lumbar vertebrae may result in mixed cauda equina and conus medullaris lesions (Fig. 157.1).

Symptoms

Lumbosacral SCI may be manifested with weakness in the lower extremities, numbness and tingling, bladder and bowel disturbances (urinary retention, constipation, bladder or bowel incontinence), impotence, back pain, and burning perianal or lower extremity pain.

FIGURE 157.1 Discrepancy between spinal cord segments and vertebral levels due to difference in lengths of the vertebral column and spinal cord.

In the outpatient setting, patients may also present with secondary conditions and associated problems, such as urinary tract infections or pressure ulcers. Patients with SCI may have vague, atypical, or nonspecific symptoms. Classic symptoms of urinary tract infection, such as urinary frequency, urgency, and dysuria, may be absent, and patients may present instead with an increased frequency of spontaneous voiding or increased muscle spasms [5]. Fever and

malaise may be indicative of a urinary tract infection but can also be due to other infections (such as osteomyelitis underlying a pressure ulcer) or noninfectious causes, such as osteoporotic long bone fracture, deep venous thrombosis, heterotopic ossification, or drug fever (e.g., due to antibiotics). Unilateral leg swelling may be the only presentation of osteoporotic lower limb fractures but could also be due to deep venous thrombosis, heterotopic ossification, hematoma, or cellulitis in the setting of SCI [6].

Pain is a common symptom in people with SCI, and some studies suggest that pain prevalence may be even higher with paraplegia than with cervical injury and tetraplegia [7,8]. A comprehensive history of pain characteristics is needed to accurately determine the underlying cause, which may be nociceptive, neuropathic, or a combination of both.

New weakness or sensory deficits in the upper extremities may indicate post-traumatic syringomyelia extending into the cervical spinal cord or a peripheral nerve entrapment, such as the median nerve at the carpal tunnel or ulnar nerve at the elbow [9]. Patients with chronic SCI who present with extension or worsening of lower extremity weakness or numbness may have post-traumatic syringomyelia or spinal cord or nerve root compression due to progressive spinal deformity or instability.

Rectal bleeding is often caused by hemorrhoids but may be a manifestation of more serious disease, such as colorectal cancer [10]. Similarly, hematuria may be due to urinary tract infection, stones, or catheter-induced trauma, but bladder cancer should be considered in the differential diagnosis, especially in smokers and those with chronic indwelling bladder catheters [5].

Mood disturbances are common in SCI [11]. Depression may be manifested with somatic symptoms such as appetite change and sleep disturbance, although symptoms like loss of energy may be difficult to interpret in the setting of SCI [11,12]. Because many medical diseases may produce similar somatic symptoms, it is helpful to inquire about specific symptoms typically associated with depression, such as suicidal thoughts, dysphoria, and feelings of hopelessness and worthlessness. Early morning awakening is suggestive of primary depression, and fatigue caused by depression is often worse in the morning.

Physical Examination

Spinal Inspection and Palpation

There may be reduced lumbar lordosis due to muscle spasm from pain. Spine fractures may result in deformity, and palpation may reveal areas of tenderness.

Evidence of Concurrent Injuries

Concurrent injuries, including head injury, extremity fractures, and abdominal visceral injury, may accompany lumbosacral SCI and should be considered during diagnostic examination.

Neurologic Examination

Neurologic examination is conducted in accordance with the *International Standards for Neurological and Functional*

Classification of Spinal Cord Injury published by the American Spinal Injury Association [1]. The neurologic findings may sometimes be subtle (e.g., limited to perineal anesthesia or urinary retention) and can be missed in the setting of acute trauma with routine placement of an indwelling catheter or drug-induced sedation, unless they are carefully considered [13]. The neurologic examination should be repeated at regular intervals to monitor for improvement or deterioration [14].

Sensory Examination

The required portion of the sensory examination is completed through testing of key points in each dermatome on the right and left sides of the body (Table 157.1) for pinprick (tested with a disposable safety pin) and light touch sensation (tested with cotton). Pinprick and light touch sensation are separately scored at each key point on a 3-point scale: 0, absent; 1, impaired; and 2, normal. In testing for pinprick sensation, inability to distinguish dull from sharp sensation is graded 0.

Motor Examination

Muscle strength is graded on a 6-point scale of 0 to 5; 0 is no contraction and 5 is normal strength. For the lumbosacral myotomes, five key muscle groups are tested bilaterally (Table 157.2).

Table 157.1 Key Sensory Points for Lumbosacral Spinal Segments

Level	Key Sensory Point
T12	Inguinal ligament at midpoint
L1	Half the distance between T12 and L2
L2	Mid anterior thigh
L3	Medial femoral condyle
L4	Medial malleolus
L5	Dorsum of the foot at the third metatarsophalangeal joint
S1	Lateral heel
S2	Popliteal fossa in the midline
S3	Ischial tuberosity
S4-S5	Perianal area (taken as one level)

Table 157.2 Key Muscle Groups for Lumbosacral Myotomes

Level	Muscle Group	Position for Testing Key Muscles for Grades 4 and 5
L2	Hip flexors (iliopsoas)	Hip flexed to 90°
L3	Knee extensors (quadriceps)	Knee flexed to 15°
L4	Ankle dorsiflexors (tibialis anterior)	Full-dorsiflexed position of the ankle
L5	Long toe extensors (extensor hallucis longus)	First toe fully extended
S1	Ankle plantar flexors (gastrocnemius, soleus)	Hip in neutral rotation, knee fully extended, and ankle in full plantar flexion

Neurologic Rectal Examination

Neurologic rectal examination includes determination of deep anal sensation and testing for voluntary contraction of the external anal sphincter around the examiner's finger (graded as present or absent). If there is voluntary contraction of the anal sphincter, the patient has a motor incomplete injury.

Additional Neurologic Examination

In addition to these required elements for neurologic classification of SCI, position and deep pressure sensation and muscle strength of additional lower extremity muscles, such as medial hamstrings and hip adductors, are also tested. Examination also includes assessment of muscle stretch reflexes, muscle tone, anal sphincter tone, bulbocavernosus reflex, and plantar reflexes.

Conus Medullaris and Cauda Equina Injuries

The examination will vary with the level of damage and the relative involvement of the conus and cauda equina and may include evidence of lower or upper motor neuron involvement. Patients with injury above the conus medullaris typically present with signs consistent with upper motor neuron or suprasacral SCI, whereas those with injury below this level present with a clinical picture consistent with lower motor neuron impairment. Lesions affecting the transition between the two regions (typically around L1 vertebral-level injury) can have a mixed picture. Conus medullaris lesions typically result in impaired sensation over the sacral dermatomes (saddle and perineal anesthesia), lax anal sphincter with loss of anal and bulbocavernosus reflexes, and sometimes weakness in the lower extremity muscles. Cauda equina involvement results in asymmetric atrophic, areflexic paralysis, radicular sensory loss, and sphincter impairment [1,13].

Skin Examination

Skin examination is conducted with particular attention to the areas most vulnerable to pressure ulcer development. These include the sacrum-coccyx, heels, trochanters, and ischial tuberosities [15].

Functional Limitations

Lumbosacral SCI can result in significant functional deficits. These include impaired mobility due to lower extremity paralysis and bladder, bowel, and sexual dysfunction due to autonomic dysregulation.

Expected Functional Outcomes

Predictions of function can be based on completeness and level of injury. The Consortium for Spinal Cord Medicine has developed clinical practice guidelines on outcomes after SCI with expected functional outcomes for each level of injury in a number of domains [14]. Expected outcomes for complete lumbosacral SCI are summarized in Table 157.3.

Ambulation

Persons with lumbosacral SCI should generally be independent at the wheelchair level and have the greatest

Table 157.3 Expected Functional Outcomes for Motor Complete Lumbosacral Spinal Cord Injury

Domain	Expected Functional Outcome	Equipment
Bowel	Independent	Padded toilet seat
Bladder	Independent	
Bed mobility	Independent	Full to king size standard bed
Bed and wheelchair transfers	Independent	
Pressure relief	Independent	Wheelchair pressure relief cushion
Wheelchair propulsion	Independent indoors and outdoors	Manual lightweight wheelchair
Standing and ambulation	Standing: independent	Standing frame
	Ambulation: functional, some assist to independent	Knee-ankle-foot orthosis or ankle-foot orthosis
	L1-L2: household ambulation	Forearm crutches or cane as indicated
	L3-S5: community ambulation	
Eating, grooming, dressing, and bathing	Independent	Padded tub bench
Communication		Hand-held shower
Transportation	Independent in car, including loading and unloading wheelchair	Hand controls
Homemaking	Independent complex cooking and light housekeeping, some assist with heavy housekeeping	

Modified from Consortium for Spinal Cord Medicine. Outcomes Following Traumatic Spinal Cord Injury. Clinical Practice Guidelines for Health Care Professionals. Washington, DC, Paralyzed Veterans of America, 1999.

potential for ambulation. If hip flexors and knee extensors demonstrate even minimal strength in the first few days after injury, functional recovery and community ambulation are likely. It has been reported that to ambulate independently after SCI, individuals need pelvic control, grade 3/5 (antigravity) hip flexor strength bilaterally to advance the lower extremities, and antigravity knee extensor strength on at least one side (so that no more than one knee-ankle-foot orthosis is needed) [16]. There is individual variation and additional factors than have an impact on ambulation outcome, but patients with motor complete lumbosacral SCI at the L1-L2 level can in general be expected to be household ambulators; community ambulation is an appropriate goal at L3-S5 levels. The lower extremity motor score can predict the likelihood of ambulation. In those with complete paraplegia, chance of walking at 1 year is less than 1% with a 30-day score of 0 and 45% with a score of 1 to 9. In those with incomplete paraplegia, chance of walking at 1 year is 33% with a score of 0, 70% with a score of 1 to 9, and 100% with a score above 10 [16].

Bowel, Bladder, and Sexual Dysfunction

Bowel, bladder, and sexual dysfunction may be significantly disabling in these patients. SCI above the sacral segments is typically associated with an upper motor neuron or reflexic bowel; lesions involving the S2-S4 anterior horn cells or cauda equina have areflexic or lower motor neuron bowel characterized by slow stool propulsion, dry and round stool referred to as scybalous, and risk of incontinence due to denervation of the external anal sphincter [10,17]. Depending on the location of injury and the extent of upper and lower motor neuron impairment, hyperreflexic, areflexic, or mixed type of neurogenic bladder may occur. Absent bulbocavernosus reflex and muscle stretch reflexes in the lower extremities suggest the likelihood of lower motor neuron impairment of the bladder and bowel. Sexual dysfunction is frequent [18]. Men with SCI at the sacral level often lose ability to have reflex erections,

although psychogenic erections may be preserved in some. Ejaculation is often impaired, but it may be preserved in a higher proportion of those with incomplete lower motor neuron injuries.

Factors Affecting Functional Outcomes

Pain, whether nociceptive or neurogenic, may interfere with function [7,19]. Neuropathic pain is more common with cauda equina injuries than with injury limited to the conus medullaris. Age, concurrent injuries or comorbidities, body habitus, psychosocial and cultural factors, and personal goals and motivation can significantly affect functional outcomes.

Diagnostic Studies

Spinal Imaging

Radiologic and laboratory studies are used to localize the site of the pathologic change and the underlying cause [13]. Plain radiographs typically include anteroposterior, lateral, and oblique views. The entire spine should be visualized because multiple levels of injury are not unusual. Computed tomographic scanning allows optimal visualization of bone injury and canal occlusion due to bone fragments. Magnetic resonance imaging is especially helpful because of its ability to visualize the soft tissues, including ligamentous structures, intravertebral discs, epidural or subdural hematomas, and hemorrhage or edema in the spinal cord. Magnetic resonance imaging with gadolinium is helpful in diagnosis of post-traumatic syringomyelia.

Electrodiagnostic Testing

Electromyography and nerve conduction studies may be helpful in distinguishing lesions of the spinal cord or cauda equina from those of the lumbar plexus or peripheral nerves.

Urologic Studies

Urodynamic studies are useful to assess the type and extent of neurogenic bladder and sphincter dysfunction. Periodic cystoscopy may be indicated in those with chronic indwelling urinary catheters because of increased risk of bladder cancer [20]. Studies to evaluate upper urinary tracts in patients with neurogenic bladder include renal ultrasonography, renal scan, abdominal radiography, and abdominal computed tomography, but there is no current consensus on the type, indication, or frequency of these tests.

Differential Diagnosis

Lumbar spinal stenosis with spinal cord or cauda equina compression
 Primary or metastatic spinal tumors
 Spinal infections or abscess
 Lesions of the lumbosacral plexus
 Disorders involving multiple nerves (e.g., polyneuropathy, Guillain-Barré syndrome)

Treatment

Initial

Initial management [13] of anyone thought to have sustained spinal injury includes adequate spinal immobilization, with placement on a board in the neutral supine position. Stabilization of the airway and hemodynamic status takes precedence in the setting of acute trauma. Methylprednisolone has been advocated in patients presenting within 8 hours of SCI, although effectiveness of this pharmacologic intervention is not uniformly accepted.

Rehabilitation

Information about potential for motor recovery can be used to set functional goals and to plan for equipment needs (see Table 157.3), keeping in mind that individual factors and coexisting conditions may affect achievable goals [14]. Important elements of rehabilitation include an interdisciplinary approach, establishment of an individualized rehabilitation program with consideration of unique barriers and facilitators, and inclusion of the patient as an active participant in establishment of goals [16].

Bowel Management

An individualized bowel care program should be established [10,17]. For upper motor neuron (reflexic) bowel dysfunction, this includes digital rectal stimulation. For lower motor neuron (areflexic) bowel dysfunction, reflex stimulation will not be effective; digital manual evacuation by gloved lubricated fingers is needed, along with Valsalva maneuver or abdominal massage to increase pressure around the colon to push the stool out. Manual disimpaction is aided by use of bulking agents to keep stool consistency firm.

Bladder Management

Optimal bladder management minimizes urinary tract complications, preserves upper urinary tracts, and is compatible with the individual's lifestyle [20]. Because hand function is intact in individuals with lumbosacral injuries, they

should be able to perform intermittent catheterization if it is needed for bladder management. If there is abnormal urethral anatomy, poor cognition or unwillingness to adhere to the catheterization schedule, or high fluid intake with consistently large bladder volumes, indwelling catheterization may be needed. Condom catheters can be an appropriate option for urinary drainage in men, provided low-pressure and complete voiding can be documented. For patients with lower motor neuron injuries with low outlet resistance, the use of Credé and Valsalva maneuvers may be considered.

In patients with suspected urinary tract infection, empirical antibiotic treatment may be started while waiting for urine culture results and modified as needed once results are available [5]. The presence of urinary tract obstruction, stones, reflux, abscess, or prostatitis should be considered if the patient fails to respond to antibiotic therapy or has a rapid recurrence with the same organism. Use of prophylactic antibiotics is usually not warranted but should be considered before urologic testing that involves instrumentation, especially in the presence of bacteriuria. Antibiotics to treat asymptomatic bacteriuria in patients with chronic indwelling bladder catheters are generally not indicated.

Pain and Spasticity

Noiceptive causes of pain should be identified and addressed [19]. Many medications, including anticonvulsants and tricyclic antidepressants, have been tried and may help in management of neuropathic pain after SCI, but none has been shown to be consistently effective. Nonpharmacologic interventions and education of the patient are important and should not be ignored. Transcutaneous nerve stimulation may help pain originating at the level of injury. Opioid prescription may be needed for pain unresponsive to other measures. Minimization of extreme or potentially injurious positions at all joints, reduction in the frequency of repetitive upper extremity tasks, proper instruction in transfer techniques to minimize upper extremity injury, optimal wheelchair selection and training, and incorporation of upper body flexibility and resistance exercises are important in preserving upper extremity function and reducing chronic pain due to upper extremity overuse [21].

Spasticity is less of a problem in lumbosacral SCI than in cervical or high thoracic injuries. Management of spasticity [22] includes elimination of the underlying noxious stimulus, use of physical interventions, systemic medications, chemical denervation, intrathecal agents, and rarely orthopedic or neurosurgical procedures. Nonpharmacologic interventions include positioning and stretching (e.g., prone lying to stretch hip flexors and stretching of hamstrings and heel cords to prevent tightness and contractures). Several medications are used for treatment of SCI-related spasticity, including baclofen, tizanidine, gabapentin, and benzodiazepines [23].

Pressure Ulcer Prevention

Education of the patient is critical in this area (see Chapter 148). Avoidance of prolonged positional immobilization, institution of pressure relief, and prescription of pressure-reducing seating systems and support surfaces are important in prevention of pressure ulcers. Daily comprehensive skin inspections should be carried out with particular attention to vulnerable insensate areas (e.g., sacrum-coccyx,

ischii, trochanters, heels). Adequate nutritional intake and smoking cessation should be stressed [15].

Procedures

Spasticity

Motor point or nerve blocks with phenol or alcohol may be helpful in treatment of localized lower extremity spasticity (e.g., for hip adductors or ankle plantar flexors) that interferes with positioning, mobility, or hygiene. Intramuscular injections of botulinum toxin are another option.

Pain

Shoulder pain due to subacromial bursitis may be temporarily responsive to local corticosteroid injections, as is the discomfort from carpal tunnel syndrome.

Pressure Ulcers

Sharp débridement of pressure ulcers may be done at the bedside to remove necrotic tissue, although if it is extensive, débridement may need to be done in the operating room.

Surgery

Spine

When thoracolumbar fractures associated with lumbosacral SCI are accompanied by mechanical instability, pain, deformity, or progressive neural impairment, surgical decompression and segmental instrumentation may be indicated for reconstruction of spinal alignment, stability, and early mobilization [13,24]. The ideal timing of and indications for surgical intervention remain controversial.

Pressure Ulcers

Plastic surgery may be indicated for deep pressure ulcers. This includes excision of the ulcer and surrounding scar and muscle and musculocutaneous flap closure [4].

Upper Extremity Pain

Surgery may sometimes be considered for chronic upper extremity overuse-related symptoms that are unresponsive to medical and rehabilitative treatment (e.g., for carpal tunnel syndrome or rotator cuff disease). Outcomes are often poor, especially if upper extremity overuse continues [21].

Bladder and Bowel Dysfunction

Surgical treatment of urolithiasis includes cystoscopic removal of bladder stones, lithotripsy, and percutaneous nephrolithotomy for larger renal stones. Endourethral stents or transurethral sphincterotomy may be considered in individuals with detrusor-sphincter dyssynergia [20]. Patients with neurogenic bowel who have significant difficulty or complications with typical bowel care may be candidates for colostomy. This decision requires careful selection of the patient and individualization to make sure that it is appropriate [17].

Post-traumatic Syringomyelia

Surgical placement of shunts may be indicated for post-traumatic syringomyelia associated with intractable pain or progressive neurologic decline.

Potential Disease Complications

Patients with lumbosacral SCI are prone to multiple complications. Urinary tract infections and pressure ulcers are two of the most common causes of hospitalization in individuals with paraplegia and can result in systemic sepsis [25]. Delayed neurologic deterioration may be due to spinal instability, progressive spinal deformity, or post-traumatic syringomyelia. Upper extremity overuse can result in shoulder pain due to rotator cuff injury or entrapment neuropathies, such as carpal tunnel syndrome [21]. Lower extremity joint contractures (e.g., of the heel cords) can interfere with mobility and with wheelchair positioning. Untreated high bladder pressure in patients with detrusor-sphincter dyssynergia or low bladder compliance may result in upper urinary tract damage. Potential complications of neurogenic bowel include anorectal problems (hemorrhoids, fissures), toxic megacolon, and colonic perforation.

Potential Treatment Complications

Neurologic deterioration may occur from inadequate spinal immobilization or as a complication of surgical instrumentation. Other surgical complications include dural tears with cerebrospinal fluid leaks, infections at the surgical site, pseudarthrosis (which may cause progressive deformity), and chronic pain.

Because people with SCI are often prescribed multiple medications (e.g., to treat pain, spasticity, and bladder or bowel dysfunction), medication-related side effects and complications are common. Complications of urethral catheterization include urethral trauma, erosions, strictures, urinary infections, and epididymitis [20]. Chronic indwelling catheters increase the risk of stones and squamous cell carcinoma of the bladder.

CHAPTER 158

Stroke

Joel Stein, MD

Synonyms

Cerebrovascular accident
Brain attack

ICD-9 Codes

- 430 Subarachnoid hemorrhage
- 431 Intracerebral hemorrhage
- 432 Other and unspecified intracranial hemorrhage
- 433 Occlusion and stenosis of precerebral arteries
- 434 Occlusion of cerebral arteries
- 435 Transient cerebral ischemia
- 436 Acute but ill-defined cerebrovascular disease
- 437 Other and ill-defined cerebrovascular disease
- 438 Late effects of cerebrovascular disease

ICD-10 Codes

- I60.9 Nontraumatic subarachnoid hemorrhage
- I61.9 Nontraumatic intracerebral hemorrhage
- I62.9 Nontraumatic intracranial hemorrhage
- I65.9 Occlusion and stenosis of precerebral artery
- I66.9 Occlusion and stenosis of unspecified cerebral artery
- G45.9 Transient cerebral ischemic attack, unspecified
- I67.89 Other cerebrovascular disease
- I67.9 Cerebrovascular disease, unspecified
- I69.30 Unspecified sequelae of cerebral infarction

Definition

Stroke is an acquired injury of the brain caused by occlusion of a blood vessel or inadequate blood supply leading to infarction or a hemorrhage within the parenchyma of the brain. Ischemic stroke is most commonly due to atherosclerosis of large extracranial or intracranial blood vessels, hypertensive disease of small vessels (lipohyalinosis), or embolism from cardiac or other sources. Approximately 15% of strokes in the United States are hemorrhagic, resulting most commonly from hypertensive hemorrhages, aneurysms, vascular malformations, or cerebral amyloid angiopathy. Approximately 800,000 strokes occur annually in the United States, with a large population of survivors with permanent disability. Important modifiable risk factors for ischemic stroke include hypertension, smoking, diabetes, obesity, sedentary lifestyle, and hyperlipidemia; nonmodifiable risk factors include age, sex, and race/ethnicity. Risk factors for hemorrhage include hypertension and smoking as well as alcohol consumption.

Symptoms

The symptoms of stroke depend on the location of the injury in the brain. For example, a stroke in the distribution of the left middle cerebral artery will typically result in right hemiplegia, aphasia, and right homonymous hemianopia, whereas a lacunar infarct in the left internal capsule may result in a less severe degree of right-sided hemiparesis and few other symptoms. Left hemispatial neglect and impaired attention are common features of right hemispheric stroke. Ischemic strokes generally conform to the vascular territory of a specific artery within the brain and therefore result in characteristic combinations of neurologic impairments that constitute a particular stroke syndrome.

In general, difficulties in walking, performing activities of daily living, speaking, and swallowing are common manifestations of stroke. Cognitive impairments (memory, attention, visual-spatial perception) and impaired communication due to aphasia or dysarthria may be present. Impaired sexual function should be identified because patients may not volunteer functional impairments in this area unless the physician inquires. Loss of libido is common among both stroke survivors and their spouses or other partners and appears multifactorial in origin. Erectile dysfunction in men may result from comorbid conditions (such as diabetes or atherosclerosis), with frequent contributions from side effects of medications including antihypertensives, antidepressants, and anticonvulsant medications.

Weakness, difficulty in speaking or swallowing, aphasia, cognitive disturbance, sensory loss, and visual disturbance are the most common presenting symptoms of stroke, and deficits in these areas often persist even after initial rehabilitation. Weakness (typically hemiparesis) results from loss of motor control primarily, and some stroke survivors retain good strength despite limited ability to perform isolated precise movements of the affected side. Urinary urgency, increased muscle tone, fatigue, depression, and pain are symptoms that may be manifested after a stroke has already occurred. Reflex sympathetic dystrophy (also known as complex regional pain syndrome type I) may occur after stroke, although most post-stroke pain results from mechanical (e.g., joint subluxation) or central (e.g., thalamic pain syndromes) causes.

Depression is common after stroke, affecting as many as 40% of stroke survivors. Depression should be identified as a treatable complication of stroke rather than accepted as a consequence of functional loss.

Physical Examination

A full neurologic examination is appropriate. This includes evaluation of mental status, cranial nerves, sensation, deep tendon reflexes, abnormal reflexes (e.g., Babinski), motor strength and coordination, muscle tone, and functional mobility (sitting, transfers, and ambulation). The protean manifestations of stroke can cause many different combinations of abnormalities in these aspects of the neurologic examination. Common findings include hyperreflexia and hemiparesis on the affected side, with variable degrees of sensory loss. Dysarthria may be present, as can aphasia or hemineglect, depending on the areas affected. Hemiplegic gait is commonly seen, with reduced stride length, reduced knee flexion ("stiff-legged gait"), ankle plantar flexion and inversion, and circumduction to allow clearance of the affected leg. An assessment of mood and affect is important, given the high prevalence of post-stroke depression. Some degree of sadness is typically present as a normal grief reaction to a sudden disabling event and should be distinguished from true major depression on the basis of how pervasive the symptoms are and associated symptoms such as anhedonia. Emotional lability may also occur, with symptoms that tend to be fleeting and changeable. Range of motion in affected limbs should be measured; ankle plantar flexion contractures and upper limb contractures are common in patients with long-standing hemiplegic stroke and interfere with rehabilitation efforts. Shoulder subluxation may occur in hemiparetic patients and should be noted and quantified. Skin is examined for any areas of breakdown. Limb swelling is common and should be noted. The fit and function of leg braces, upper extremity splints, slings, wheelchairs, and ambulatory aids are assessed as part of the routine physical examination.

Functional Limitations

Depending on the impairments that patients have, they may be unable to drive or to use public transportation. Communication difficulties can lead to social isolation. Some individuals require ongoing supervision because of cognitive limitations. In severe cases, individuals with

aphasia or cognitive impairments may not be able to live independently. Incontinence due to detrusor instability and urinary urgency can interfere with leaving the home and contribute to skin breakdown and social isolation.

Among stroke survivors older than 65 years who were evaluated 6 months after a stroke, 30% were unable to walk without some assistance, 26% were dependent for activities of daily living, and 26% were institutionalized in a nursing home [1].

Diagnostic Studies

In the acute setting, computed tomography is often the first diagnostic test performed because of the rapidity with which it can be obtained, its widespread availability, and its high sensitivity for cerebral hemorrhage. Magnetic resonance imaging provides greater anatomic resolution and avoids radiation exposure. With diffusion and perfusion-weighted sequences, magnetic resonance imaging abnormalities can be demonstrated at a very early stage, providing important information for acute treatments such as thrombolysis [2]. Magnetic resonance angiography, computed tomographic angiography, noninvasive flow studies, Holter monitoring, and echocardiography are important studies to help determine the cause of a stroke and to determine the best treatment for prevention of recurrent stroke. In selected patients (particularly young individuals or those without typical risk factors), an evaluation for a hypercoagulable state is indicated. In patients with prior stroke, diagnostic studies are typically directed to complications of stroke, such as persistent dysphagia or urinary incontinence. Videofluoroscopic swallowing studies can be useful in swallowing disorders, as can flexible endoscopic evaluation of swallowing. Urodynamic studies may be useful in the assessment of urinary symptoms, particularly if initial treatment with anticholinergic medications is unsuccessful.

Differential Diagnosis

- Hemiplegic migraine
- Post-seizure (Todd) paralysis
- Brain neoplasm
- Multiple sclerosis

Treatment

Initial

When ischemic stroke is diagnosed within the first 3 hours, thrombolytic therapy has been shown to reduce disability [3]. There is evidence that thrombolysis may be useful in selected individuals between 3 and 4.5 hours after stroke onset as well [4]. Mechanical clot retrieval and intra-arterial thrombolysis have been used successfully for patients who do not experience resumption of flow in the occluded artery with intravenous thrombolysis or who fall outside of the time window for this therapy [5]. Aspirin (between 80 and 325 mg) has been found to be effective when it is used in the acute setting. In younger patients with large ischemic strokes, increased intracranial pressure due to swelling may require hemicraniectomy to prevent herniation and death.

Secondary prevention depends on the cause of the stroke. Warfarin (Coumadin) is commonly used for the secondary prevention of embolic stroke, with the most extensive evidence for prevention of stroke in atrial fibrillation. Several new oral anticoagulants are increasingly used as alternatives to warfarin, including dabigatran (Pradaxa), apixaban (Eliquis), and rivaroxaban (Xarelto) [6,7]. Antiplatelet agents, including aspirin, clopidogrel (Plavix), or a combination of aspirin and dipyridamole (Aggrenox), are used for prevention of most non-cardioembolic strokes or when anticoagulation is desirable but contraindicated because of comorbid conditions. Risk factor modification, including treatment of hypertension, diabetes, hyperlipidemia, and obesity as well as smoking cessation and exercise, should be addressed for all stroke survivors.

Treatment of cerebral hemorrhage is based in part on the presumed cause. For hypertensive hemorrhages, control of blood pressure with antihypertensive medications is the mainstay of treatment. Large hemorrhages may require hematoma evacuation and removal of a portion of the skull to treat elevated intracranial pressure. For all causes of cerebral hemorrhage, avoidance of anticoagulants, antiplatelet medications, and alcohol is important.

Medications for the management of post-stroke symptoms on an outpatient basis are shown in Table 158.1. Anticholinergic medications are useful for bladder detrusor instability. Oral antispasticity medications are of limited efficacy in many cases (see Chapter 153). For sexual dysfunction in men, phosphodiesterase type 5 inhibitors may be effective. Treatment with selective serotonin reuptake inhibitors for post-stroke depression is widely employed, although a wide range of antidepressant medications can be effective. Psychostimulants (e.g., methylphenidate) and eugeroics (e.g., modafinil) may be useful for impaired attention. Anticonvulsants are used for central pain syndromes, but with variable benefit.

Rehabilitation

The rehabilitation program needs to be customized on the basis of the severity and nature of the impairments caused by the stroke. For individuals with moderate to severe stroke,

a comprehensive multidisciplinary inpatient rehabilitation program in a rehabilitation hospital is often appropriate and may lead to improved outcomes [8]. Stroke patients with significant functional limitations in mobility, communication, cognition, or self-care who are capable of participating in and benefiting from an intensive rehabilitation program consisting of 3 hours or more of rehabilitation therapy per day commonly undergo an inpatient rehabilitation stay. For these individuals, rehabilitation commonly continues through home care or outpatient services after discharge from the rehabilitation hospital/unit. Patients with more circumscribed and less severe deficits may be discharged directly from the acute care hospital to home and participate in an outpatient rehabilitation program [9]. Patients who are unable to participate in an aggressive rehabilitation program because of poor motivation, severe cognitive deficits, or poor prognosis may receive inpatient rehabilitation at a subacute program (skilled nursing facility) instead, as may some patients with milder deficits who are unable to be discharged directly home. There is considerable practice variation regarding referral to an inpatient rehabilitation facility versus a skilled nursing facility and only limited observational data comparing outcomes in the two types of facilities [8,10]. Although not definitive, these studies suggest better outcomes for patients receiving inpatient care, and stroke patients who meet the admission criteria and have insurance coverage for this type of care should be preferentially referred to inpatient rehabilitation facilities when it is feasible.

Exercise

Therapeutic exercise programs are usually functionally oriented, with an emphasis on restoration of functional mobility and ability to perform activities of daily living (Fig. 158.1). Instruction in compensatory techniques and family teaching are important in assisting individuals to return home. There is growing evidence of the impact of therapeutic exercise on cortical reorganization after stroke, with associated improvements in motor control and functional use of the affected limbs [11]. Newer approaches being studied to enhance motor abilities include constraint-induced movement therapy, robot-assisted exercise training (Fig. 158.2), and virtual reality exercise training [11–14].

Table 158.1 Medications Commonly Used for Treatment of Post-Stroke Symptoms

Class of Medication	Examples	Indication
Anticholinergics	Oxybutynin (Ditropan)	Bladder detrusor instability
Antispasticity	Tolterodine (Detrol)	Muscle spasticity
	Baclofen (Lioresal)	
	Tizanidine (Zanaflex)	
	Diazepam (Valium)	
	Dantrolene (Dantrium)	
Phosphodiesterase type 5 inhibitors	Sildenafil (Viagra)	Erectile dysfunction
Selective serotonin reuptake inhibitors	Vardenafil (Levitra)	Post-stroke depression
	Fluoxetine (Prozac)	
	Paroxetine (Paxil)	
	Sertraline (Zoloft)	
	Methylphenidate (Ritalin)	
Stimulants	Dextroamphetamine (Dexedrine)	Impaired attention, arousal
Eugeroics	Modafinil (Provigil)	Impaired arousal, attention
	Armodafinil (Nuvigil)	
Anticonvulsants	Gabapentin (Neurontin)	Central pain syndromes, seizure disorders
	Carbamazepine (Tegretol)	

FIGURE 158.1 The time course of recovery after stroke is shown as the cumulative percentage of stroke survivors in each category who have reached their best function in activities of daily living relative to initial functional disability: ■, mild disability; ▲, moderate disability; ●, severe disability; and ×, very severe disability. (From Jorgensen HS, Nakayama H, Raaschou HO, et al. Outcome and time course of recovery in stroke. Part II. Time course of recovery. *The Copenhagen Stroke Study. Arch Phys Med Rehabil* 1995;76:406-412.)

FIGURE 158.2 Robot-assisted upper limb exercise therapy using the ArmeoPower system (Hocoma, Zurich, Switzerland).

These novel techniques appear to improve motor function, but the optimal exercise program to facilitate recovery remains to be defined.

Electrical Stimulation

Noninvasive brain stimulation has been studied as a means of enhancing motor recovery and for treatment of aphasia

after stroke. This can be delivered by transcranial magnetic stimulation or transcranial direct current stimulation. Preliminary studies suggest benefit of this therapy when it is combined with exercises, but definitive trials have not yet been performed [15].

Dysphagia

Management of dysphagia may include nasogastric or gastrostomy tube feedings, modified diets (e.g., thickened liquids, pureed foods), and swallowing therapy (e.g., the use of compensatory strategies, such as “tucking” the chin during swallowing).

Communication

The rehabilitation of aphasia relies on extensive speech therapy as its mainstay; selected patients benefit from communication aids, such as a picture board. Speech therapy may provide significant benefit for dysarthria as well, resulting in improved intelligibility. Severely dysarthric or anarthric patients may benefit from the use of computer-based communication aids, including those with speech synthesis, as well as “low-tech” solutions, such as spelling boards.

Cognition

Cognitive abilities are frequently affected by stroke; alterations in memory, attention, insight, and problem solving are common. Neuropsychological testing may be useful in defining the precise nature of these deficits and in helping to develop a remediation plan. Speech-language and occupational therapy approaches include attempts at remediation and teaching of compensatory techniques. Family education and training are important components of cognitive rehabilitation. Recognition and treatment of post-stroke depression are important because depression can contribute to reduced cognitive performance after stroke [16].

Bracing

Lower extremity bracing is frequently helpful in restoration of mobility in hemiparetic stroke survivors. Most commonly, a plastic or carbon-fiber ankle-foot orthosis is used,

although other braces are appropriate in selected circumstances. Bracing is helpful as a compensation for impaired ankle dorsiflexion, controlling ankle inversion and plantar flexor spasticity as well as providing some stabilization at the knee. Electrical stimulation systems (e.g., Bioness L300, WalkAide) can be used to stimulate dorsiflexion as an alternative to a brace for selected patients.

Ambulatory Aids and Wheelchairs

Because of hemiparesis, many stroke survivors require ambulatory aids, which may include a straight cane, a four-pronged ("quad") cane, a hemi-walker, or, in some cases, a conventional walker. Wheelchairs are often needed for more severely impaired stroke survivors or for moderately impaired stroke survivors for longer distance travel. A hemi-wheelchair is lower to the ground and allows use of the nonparetic leg to assist with propulsion. On occasion, a one-arm drive wheelchair is useful; it allows control of both wheelchair wheels from one side. Active, nonambulatory individuals may benefit from a power wheelchair.

Shoulder Subluxation

Shoulder subluxation commonly occurs in the setting of hemiplegia after stroke, although the presence of pain is highly variable. Arm boards and the selective use of slings help in reducing subluxation. Electrical stimulation may have a beneficial effect as well [17].

Splints

Splints for proper positioning of the hemiplegic arm and ankle-foot are important to prevent contracture. These are particularly important when spasticity is present. Failure to properly splint and stretch the hand and wrist can result in progressive contracture leading to deformity, even with relatively mild spasticity.

Vocational Rehabilitation

Although stroke is predominantly a disease of older individuals, a significant portion of stroke survivors are of working age. Once activities of daily living have been mastered, vocational counseling may assist individuals seeking to return to work. Coordination with the rehabilitation team is important because retraining for certain job tasks may involve a multidisciplinary effort. Accommodations in the workplace may be necessary, and the Americans with Disabilities Act may require the employer to provide reasonable accommodation for individuals with disabilities.

Procedures

Botulinum toxin or phenol injections may be useful in the management of spasticity after stroke. These injections are described in greater detail in Chapter 153.

Surgery

Selected patients require craniotomy in the acute phase for evacuation of a large intracerebral hematoma or for severe swelling with increased intracranial pressure. Carotid endarterectomy or stenting in appropriately selected patients has been shown to reduce the risk of recurrent stroke [18]. Intrathecal baclofen pumps have been found to be effective

in treatment of post-stroke spasticity [19,20] but are infrequently used for hemiplegic stroke at this time. In patients with chronic impairments from stroke, tendon lengthening procedures are occasionally needed for contractures.

Potential Disease Complications

Seizures can develop as an early or a late complication of stroke; strokes involving the cerebral cortex and hemorrhagic stroke carry greater risk. The risk of deep venous thrombosis is substantially elevated in hemiplegic stroke, and prophylactic treatment with subcutaneous heparin or low-molecular-weight heparin is advisable during the initial recovery phase [21]. The ideal duration of prophylaxis for deep venous thrombosis after stroke has not been established; in most cases, this is discontinued after a period of several weeks. Stroke recurrence is a feared complication of stroke, and individuals with a history of stroke remain at increased risk for recurrent stroke despite risk factor reduction. Aspiration pneumonia can occur as a complication of dysphagia, although this risk tends to abate over time except in the most severe cases.

Potential Treatment Complications

Both anticoagulants and antiplatelet medications can contribute to bleeding complications. Aspirin can cause gastritis. Clopidogrel has been associated with thrombotic thrombocytopenic purpura. The combined use of aspirin and clopidogrel does not provide additional protection against stroke but increases the risk of gastrointestinal hemorrhage [22].

Anticholinergic medications commonly cause dry mouth and may precipitate urinary retention. Antispasticity medications can cause sedation and may exacerbate cognitive impairments. Sildenafil is known to be hazardous when it is used concurrently with nitrates and should be avoided in patients receiving these medications. Selective serotonin reuptake inhibitors can cause gastrointestinal symptoms (especially nausea and anorexia) as well as interfere with libido and sexual function. Psychostimulants can cause anorexia, insomnia, anxiety, or agitation and should be slowly titrated upward. Gabapentin is usually well tolerated, although occasional sedation has been reported. Carbamazepine may cause leukopenia.

Definition

Four percent of strokes in the United States occur in adults younger than 45 years, and a collective review of reports provides estimates that range up to 21% or greater [1]. Although the 28,000 strokes in this age group are a small fraction of the 731,000 total events in the United States

each year, stroke is an important cause of neurologic impairment in this group. Stroke occurs in those younger than 45 years more than twice as frequently as spinal cord injury (11,000 per year, all ages), and yet there has been limited awareness in American society of stroke as a disease affecting younger adults. *As overall stroke incidence declines, there is evidence that stroke is occurring at a younger age, with the incidence increasing in younger adults* [2]. Before the age of 30 years, more women than men have strokes because of the risks of pregnancy, childbirth, and oral contraceptive use [3,4]; this trend reverses with advancing age. In the United States, the incidence of stroke is two to five times higher in young urban blacks and twice as high in Hispanics than in whites [5]. Strokes in young adults are particularly devastating events because they often occur in otherwise healthy-seeming individuals who are in the prime of life and fully involved with family, community, and workplace responsibilities. Young adults also have high expectations of recovery and consequent difficulty in adjusting to residual disability.

Although more than 60 different disorders causing stroke in young adults have been identified, they can be grouped into several broad categories. Atherosclerotic disease accounts for approximately 20%; cardiac emboli, 20%; arteriopathies (particularly large-vessel dissection), 10%; coagulopathy, 10%; and peripartum cerebrovascular accidents, 5%. Another 20% may be related to mitral valve prolapse, migraine, and oral contraceptive use, and 15% remain unexplained after full evaluation [6]. In American studies, illicit drug use has been associated with stroke in 4% to 12% of cases [5,7]. The main clinical challenge in the management of young adults with acute stroke is the identification of its cause. Whereas cryptogenic stroke was the most common cause in the past, today specific causes are more readily identified resultant to improved capability in noninvasive imaging of brain vessels and heart arteries and valves, aortic electrophysiology, and genetic diagnostic instruments developed in recent decades [8,9]. The rate of thrombolysis use among young acute ischemic stroke patients has increased in the past decade, in part owing to stroke center certification and the availability of the stroke networks [10].

Approximately 75% of patients younger than 65 years will survive 5 years or more after their stroke [1]. Individual survival depends, of course, on the specific cause of the stroke and its treatment. In general, two thirds of young survivors achieve good functional recovery, although a history of diabetes mellitus, severe deficit at onset, or stroke involving the total anterior circulation may reduce that likelihood. Overall, the risk for recurrence in those who have suffered a first stroke averages 5% per year and varies with the survivor's burden of risk factors [11–13].

Symptoms

The presenting neurologic symptoms of stroke are the same in young as in elderly patients and are reviewed in Chapter 158. The clinician caring for young adult stroke survivors in the post-acute phase is likely to encounter, in addition to neurologic residua of the stroke, a number of secondary symptoms that will require ongoing management. The most common of these are emotional effects, pain, spasticity, bladder dysfunction, sexual dysfunction,

and fatigue. These symptoms may also occur in older stroke patients; however, this chapter focuses on the impact they have on the young stroke survivor.

Emotional Effects

The common emotional consequences of stroke are depression, emotional lability, and anxiety. Clinical depression occurs in approximately 40% of patients after stroke; its incidence peaks 6 months to 2 years after the ictus. It is more likely in those with a prior history of alcoholism or depression and in patients who have suffered a severe stroke [14,15].

Depression can be difficult to identify in aphasic patients who cannot respond reliably to questions about mood and in patients with motor aprosodia (loss of emotional tone in facial expression and voice) due to right hemispheric stroke. Patients tend to become more socially isolated after stroke because of language, cognitive, and physical deficits. Loss of social interaction and support increases the likelihood of depression. Stress related to marital role reversal after a stroke in one member of a couple is common, as is depression in caregivers [15].

Neurologically mediated emotional lability, also known as pseudobulbar affect or emotional incontinence, in which the patient has abrupt episodes of crying or laughing in response to mention of an affectively charged topic, may be a source of distress to the patient and family. It may also complicate evaluation of the patient's true emotional state.

Patients may experience heightened anxiety chronically after stroke. In some cases, specific triggers of the anxiety, such as fear of falling while walking with a cane or fear of being left alone, can be identified in the history. The prevalence and severity of anxiety symptoms were comparable to those of depression symptoms, and the prevalence of both mood symptoms was similar during the acute period and 1 year after stroke. Both mood disturbances were also associated with a poorer health-related quality of life at 1 year, whereas only depression symptoms influenced functional recovery. More emphasis should be given to the role of anxiety in stroke rehabilitation interventions [16].

Pain

Pain is a common problem after stroke in young patients. It usually affects the hemiparetic extremities and may be centrally or peripherally mediated. Shoulder pain occurs in up to 85% of stroke patients, usually during the first 6 to 12 months after stroke [17]. The history should address its many potential causes [18] (Table 159.1). In addition, younger individuals with partially recovered motor function may have secondary sprains, tendinitis, skin breakdown, and nerve palsies in the paretic extremities as these are pushed beyond their physiologic limits in the effort to resume normal activities. The normal arm and leg may suffer similar overuse injuries in the course of compensating for the weak side. Heavy use of assistive devices, including canes, walkers, braces, and splints, may contribute to these injuries and consequent pain.

Muscle Stiffness due to Spasticity

Stiffness and heaviness of muscles and joints are common complaints of young stroke patients in the post-acute

Table 159.1 Post-Stroke Shoulder Pain [18]

Disorder	Inferior Subluxation	Rotator Cuff Tear	CRPS I (Shoulder-Hand)	Frozen Shoulder	Impingement Syndrome	Biceps Tendinitis
Examination	Acromiohumeral separation Flaccid	Positive abduction test result Positive drop arm test result Flaccid or spastic	Metacarpophalangeal joint compression test Skin color changes Flaccid or spastic	External rotation < 15 degrees Early scapular motion Spastic	Pain with abduction of 70-90 degrees End-range pain with forward flexion Spastic Subacromial injection of lidocaine	Positive Yergason test result Flaccid or spastic
Diagnostic test	Standing radiograph in scapular plane	Arthrography Subacromial injection of lidocaine Magnetic resonance imaging	Triple-phase bone scan Stellate ganglion block	Arthrography		Tendon sheath injection of lidocaine

Procedures		Steroid injection Surgical repair	Stellate ganglion block	Subacromial, intra-articular steroids Débridement Reduction of internal rotator tone	Subacromial steroids Reduction of internal rotator tone	Tendon sheath injection of steroids

AAROM, active-assisted range of motion; CRPS I, chronic regional pain syndrome type I; PROM, passive range of motion.

setting. These symptoms are often due to the evolution of muscle tone from the flaccid to the spastic state that occurs during the first several months that follow a stroke. Although it is occasionally helpful in allowing weight bearing on a leg with little voluntary motor return, spasticity more often complicates the patient's efforts to resume normal motor function. The reader is referred to Chapter 153 for further discussion of spasticity symptoms. Joint stiffness may also be due to contracture, which is shortening of the muscles, ligaments, or tendons around a joint due to rheologic changes in the tissues. This is common in the finger joints of the affected hand. Frozen shoulder, with contracture of the glenohumeral joint capsule, also occurs.

Bladder Dysfunction

Chronically diminished bladder control with urge incontinence occurs commonly in younger stroke patients. The history should ascertain chronicity and frequency of the problem, diurnal pattern, and presence or absence of the sensation of needing to void; a relationship to coughing, laughing, or straining is noted. The patient is queried about abdominal pain and pain on urination.

Sexual Dysfunction

Whether the physiologic process of sexual function changes as a result of stroke, and if so, how it changes, has not been scientifically established. Nonetheless, most patients report diminished sexual function after stroke. This may involve diminished libido or decreased erectile or ejaculatory function. Decreased libido may correlate with the presence of depression and reduced physiologic sexual function with medical comorbidity. Neither clearly relates to size or location of stroke. There is evidence that patients' partners play a significant role in the decline of sexual activity, through fear of relapse, anguish, and lack of excitement. A small number of patients report increased libido after stroke, and rarely, troublesome hypersexuality appears [19,20]. The history should note change in interest and frequency of sexual activity, alteration in ability to achieve erection or ejaculation in men and lubrication or orgasm in women, and presence of depression or active medical comorbidities that may influence sexual activity level. Medications are reviewed for antihypertensives, antidepressants, and others that may hinder sexual function and possibly fertility, although there is little research on this topic.

Fatigue

Increased fatigue after stroke has been reported in 39% to 68% of patients in published series. It is frequently influenced by coexisting depression. Young adults who never before needed naps now do. Patients become fatigued, physically and mentally, with less effort than before the stroke. Return to active work and family life may be limited by fatigue [21,22]. The history should document a change in fatigue level after the stroke and probe the daily pattern of fatigue and sleep for symptoms of insomnia, sleep apnea, and the many medical conditions that produce fatigue.

Medications are reviewed to identify sedative agents. Depression and loss of physical conditioning may affect energy levels, as may the increased energy cost of hemiplegic gait [23].

Physical Examination

In the post-acute setting, the examination of the younger patient after a stroke includes neurologic and functional status for evidence of improvement or deterioration. Improved motor control in the affected leg may allow trimming back of a brace and progression in gait training to a less supportive assistive device. Worsening motor or sensory function, on the other hand, may signal not only further cerebral events but also the presence of a systemic illness, medication intolerance, new peripheral nerve injuries related to positioning or assistive devices, or worsening neuropathy. Confrontation testing for visual fields and double sensory stimulation tests for visual and tactile neglect provide important information to the patient and physician about suitability for community mobility, particularly driving. Clock drawing, target cancellation, line bisection, and reading from a magazine can be quickly performed in the office and provide additional information about neglect and attention. The Mini-Mental State Examination is a rapid and helpful cognitive screen [24,25]. The affected arm and leg should be inspected for skin breakdown. Maceration of the palm in a tightly flexed hand and friction marks on the dorsum of the foot and calf of patients using ankle-foot orthoses are common. Ulnar palsy and olecranon bursitis related to a constantly flexed spastic elbow can occur. It is particularly important to identify and to treat these problems early in patients with diminished sensation.

Signs of unusual causative entities should be sought if the etiology of the stroke is unclear. These may include the skin laxity and hypermobility of Ehlers-Danlos syndrome, the ipsilateral ptosis and miosis (partial Horner syndrome) associated with carotid dissection, the multiple venipuncture marks of intravenous drug abuse, the livedo reticularis of Sneddon syndrome, the vasculitic rash of connective tissue diseases, and the arachnodactyly and tall habitus of Marfan syndrome.

Emotional Effects

Mood should be evaluated for signs of depression, lability, and anxiety. For patients with intact verbal function, the two questions *During the past 2 weeks, have you felt down, depressed, or hopeless?* and *During the past 2 weeks, have you felt little interest or pleasure in doing things?* may be as helpful as more extensive screening tools, such as the depression screening criteria of the *Diagnostic and Statistical Manual of Mental Disorders* [26,27]. In severely aphasic patients, the screen must, of necessity, consider facial expression, gestures, and posture and the reports of caretakers regarding appetite, sleep, and mood. If the caretaker shows signs of depression, it may be helpful to offer him or her referral for further evaluation. Lability can often be elicited by discussing affectively relevant topics, such as children or spouse. Physical examination signs of chronic anxiety may include hunched posture, fleeting eye contact, cold or moist

hands, mild tachycardia, rapid and hypophonic speech, and ready startle reaction.

Pain

The examination addresses appearance, tenderness, pain pattern, and range of motion of the painful regions, looking for signs of specific medical and musculoskeletal disorders. See [Table 159.1](#) for helpful physical examination signs in the diagnosis of post-stroke shoulder pain.

Muscle Stiffness due to Spasticity

Muscle tone at the shoulder adductors, elbow flexors and extensors, wrist and finger flexors, knee extensors, and ankle plantar flexors should be assessed and recorded at each visit with use of the Ashworth scale ([Table 159.2](#)). Pain encountered on range of motion is recorded. Reflexes are evaluated, assessing for sustained clonus, which at the ankle and knee can compromise gait and at the wrist and fingers may be mistaken for seizure activity.

Bladder Dysfunction

Palpatory examination of the abdomen may reveal suprapubic tenderness due to cystitis or an enlarged bladder indicative of retention with overflow incontinence.

Sexual Dysfunction

Full gynecologic and urologic examinations will screen for infectious, traumatic, neoplastic, and hormonal causes of sexual dysfunction in young stroke survivors. The neurologic examination may reveal a neuropathy (manifested by decreased sensation in the feet or hands, decreased ankle and knee reflexes, and occasionally distal weakness) that may be affecting sexual function.

Fatigue

Idiopathic post-stroke fatigue is a diagnosis of exclusion. The examination must screen the patient for the many illnesses that cause fatigue. Among the more prominent of these in this population are Epstein-Barr viral disease, sleep apnea, allergic rhinitis, anemia, dehydration, cerebral hypoperfusion, hypothyroidism, depression, malignant neoplasia, and medications.

Table 159.2 Modified Ashworth Scale for Measurement of Spasticity

0	No increase in muscle tone
1	Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end range of motion
1+	Slight increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the range of motion
2	More marked increase in muscle tone through most of the range of motion, but the affected part is easily moved
3	Considerable increase in muscle tone, passive movement difficult
4	Affected part is rigid in flexion or extension

Functional Limitations

Driving

Return to driving is a necessary step for return to a normal life-style and avoidance of social isolation in many communities. Once they have been discharged home, young adult stroke patients are generally eager to resume driving. Many rehabilitation clinics offer written tests of driving ability. Although these have not been shown to be adequate predictors of on-the-road performance, they serve a useful screening purpose. Recent work with a computerized driving simulator suggests that these may be helpful and safe tools for retraining of driving skills [28]. A number of factors have been shown to predict driving performance after stroke; right hemisphere location of stroke, visual-perceptual deficits, reduced sustained and selective attention, impulsivity, poor judgment, and lack of organizational skills all correlate with poor performance behind the wheel. Aphasia, although it may have a negative impact on performance on written and road tests because of compromised processing of verbal instructions, does not always interfere with self-directed driving.

Physicians are often consulted about a patient's readiness to resume driving; visual acuity and fields can be readily screened in an office setting, but evaluation for impulsivity, judgment, and selective and divided attention is more difficult. An on-the-road test performed either by a driving instructor or by the state licensing agency remains the "gold standard" for assessment of driving ability.

Return to Work

The ability to perform valued work is central to self-esteem and an important goal for most young stroke patients. Between 11% and 85% of patients achieve this goal; the wide range reported in this literature is due to differing age ranges, definitions of work, and disability compensation systems [29]. Of those who return to work after stroke, 70% do so at a reduced level. Factors predictive of success in return to work include pure motor or no hemiparesis, good self-care and mobility function at completion of rehabilitation, no aphasia or apraxia, advanced education, and a white-collar job. Barriers to successful vocational rehabilitation include, in addition to the reverse of these factors, cognitive impairment, visual-perceptual impairment, age older than 55 years, and economic disincentives related to disability and retirement benefits.

Patients who are able to resume work after a stroke on average do so within the first 6 months. The 1990 Americans with Disabilities Act has had a positive impact on employers' responsiveness to the requests of stroke survivors for job accommodations, not only regarding physical access and equipment but also for personal assistance, schedule flexibility, and task modification [29–31]. Most patients return to their previous employer, although young stroke survivors with minimal cognitive impairment may be able to take on new jobs.

Parenting

The young adult stroke survivor who needs to return to parenting faces particular challenges in the performance

of child bathing, dressing, feeding, and transporting tasks. Problem solving of these tasks can be done with the assistance of other adult family members, home care occupational therapists, or hired child care assistants. Many helpful items of equipment are readily available (paper disposable diapers with easy to close tabs, microwaves for heating bottles, baby tub inserts). Even when frequent assistance is needed, the patient should be encouraged to assume the supervisory role in child care.

Diagnostic Studies

Because the use of illicit drugs has been linked to strokes in younger individuals, ongoing drug screening in the post-acute setting may occasionally be indicated. Despite the use of early and advanced neuroimaging techniques along with improved symptom recognition by patients, misdiagnosis of acute stroke in young adults in emerging reports occurs at 14%, with posterior circulation more likely to be misdiagnosed as peripheral vertigo. The initial misdiagnosis results in a potential lost opportunity for thrombolysis or admission to certified stroke centers in otherwise good candidates [32]. For other diagnostic testing, see Chapter 158.

Differential Diagnosis

- Brain infection (abscess, encephalitis)
- Brain neoplasm
- Cranial nerve palsy
- Peripheral nerve palsy
- Hemiplegic migraine
- Multiple sclerosis
- Progressive multifocal leukoencephalopathy
- Positional vertigo
- Post-seizure (Todd) paralysis
- Toxic metabolic encephalopathy
- Conversion disorder

Treatment

The patient's motivation to comply with treatment for hypertension and diabetes, to develop a habit of compliance with newly prescribed anticoagulation therapy, to quit smoking, to avoid excessive alcohol intake, and to turn away from the use of street drugs will be maximal in the months that follow the stroke. Some available studies suggest that stroke rehabilitation should provide interventions designed especially for young adults, but more recent studies reflect that the young adult patient's needs are similar to those of the general stroke population [33].

Emotional Effects

Initial

Post-stroke depression responds to antidepressant medications of several classes. The lower cardiac risk profile of selective serotonin reuptake inhibitors makes them an attractive option for patients with arrhythmia. They should be used with caution in patients with sexual dysfunction. The sedative and urinary retentive properties of

tricyclic antidepressants may be helpful for patients with concomitant neuropathic pain, excessive salivation, and sleep disturbance or urge incontinence. All of the major classes of antidepressants have the potential to lower seizure threshold. The family and community, including local and national stroke support and education groups, are important resources for the young patient who is struggling with emotional adjustment to residual disability and altered lifestyle. Referral to a psychiatrist, psychologist, home care social worker, or psychiatric nurse is often helpful. Emotional lability often responds to selective serotonin reuptake inhibitors and usually diminishes over time [34,35]. Management of anxiety in cognitively impaired young stroke patients should emphasize the less sedating anxiolytics, counseling, and environmental manipulation to reduce known triggers.

Rehabilitation

Neurologic and functional improvement is perhaps the best antidote to post-stroke depression. A multidisciplinary stroke rehabilitation program, by providing graded and progressive activities in many areas, gives the patient the opportunity to make and to appreciate numerous improvements in parameters of mobility, self-care, language, and cognition. Therapists are skilled at providing encouragement and positive reinforcement for successes, large and small, in the targeted activities. The rehabilitation therapy environment provides substantial psychological support to the patient, and it is common for depression first to become evident, or to worsen, at the time outpatient therapy finishes and this support system is withdrawn.

Procedures

Electroconvulsive therapy may be indicated for refractory depression.

Pain

Initial

Measures for soft tissue-based pain include non-narcotic analgesics and nonsteroidal anti-inflammatory drugs, with care taken to consider the cardiac, renal, hepatic, and gastrointestinal risks. When narcotic medication for pain relief is required, the fentanyl transdermal patch is a useful option. Neuropathic and central pain syndromes often respond to gabapentin. See Table 159.1 for treatment options for the several varieties of post-stroke shoulder pain.

Rehabilitation

Rehabilitation treatment of pain syndromes is useful both in itself and because it allows close monitoring by a qualified therapist of the patient's symptoms and response to treatments. Soft tissue injuries often respond to stretching and strengthening, positioning, electrical stimulation of the affected muscles, and heat modalities including hot packs and ultrasound when sensation is adequate to allow their use. Transcutaneous electrical nerve stimulation and functional electrical stimulation to the supraspinatus and upper trapezius are often helpful in poorly defined shoulder pain, as are arm slings, such as the Harris hemi-sling, that promote optimal glenohumeral alignment.

Procedures

Acupuncture can be beneficial for central pain syndromes, and subacromial bursa steroid injection will help approximately half of patients with post-stroke shoulder pain. Botulinum toxin and phenol injections provide relief when pain is due to spasticity in specific muscles.

Surgery

In post-stroke shoulder pain, surgical repair may be considered when rotator cuff tear can be established as the cause. Surgical débridement may be required for severe, unremitting frozen shoulder.

Muscle Stiffness due to Spasticity

Initial

The management of muscle stiffness due to spasticity is discussed in detail in Chapter 153. Intercurrent infections, localized sores, stress, and anxiety can worsen spasticity and should be treated before other interventions are added. Sedation in this cognitively fragile population is to be avoided and limits dosage titration of all the available antispasticity agents. Tizanidine and gabapentin, because of their analgesic as well as muscle relaxant actions, are logical choices for painful spasticity. Selective serotonin reuptake inhibitors occasionally exacerbate spasticity.

Rehabilitation

Mild post-stroke spasticity in the heel cord and finger and wrist flexors can often be adequately controlled with a stretching program performed two or three times per day by the patient. Range of motion in a spastic ankle or hand can be preserved with nighttime use of custom-fabricated resting splints.

Procedures

Injection of spastic muscles with botulinum toxin and of peripheral motor nerves with phenol can enhance gait pattern and hand function and reduce pain in young stroke survivors. Once a pattern of useful response to injection to specific muscles and nerves has been established, consideration should be given to surgical referral for more permanent intervention.

Surgery

Tendon lengthening, sectioning, and transfers infrequently performed in elderly stroke patients because of limited life expectancy and medical risks should be considered in younger patients when the pattern of hypertonicity has stabilized. Achilles tendon lengthening may allow improved heel strike in patients with chronic equinovarus posturing due to spastic triceps surae. Sectioning of short toe flexors can reduce painful toe clawing, and splitting and lateral reattachment of a portion of the anterior tibial tendon (SPLATT procedure) can rebalance a varus foot. Electrophysiologic evaluation of the extremity in a gait laboratory can provide useful information to supplement the physical examination and help ensure that the optimal muscles are targeted for surgical intervention.

Bladder Dysfunction

Initial

For the stroke survivor with urge incontinence due to spastic neurogenic bladder, helpful medications are available. The anticholinergics oxybutynin and tolterodine are first-line agents for management of detrusor instability. In addition, tricyclic antidepressants provide mild anticholinergic stimulation and can be used to increase bladder capacity.

Rehabilitation

Urinary incontinence can be successfully managed in the inpatient rehabilitation setting or at home with timed voiding (every 2 hours while awake), timed fluid intake (none after supper), use of padded clothing or condom catheter, and a commode or urinal by the bedside.

Pelvic floor strengthening exercises are helpful for stress incontinence. There are no specific rehabilitation treatments for detrusor instability, although the patient's therapists are often in a position to observe and to document the extent of the problem.

Surgery

Bladder suspension surgery may be indicated for stress incontinence.

Sexual Dysfunction

Treatment of depression with medications such as bupropion, mirtazapine, and nefazodone, which do not hinder sexual function [36], and of active concurrent medical illnesses can promote improved sexual function. Elimination of other medications that compromise ejaculatory or orgasmic function will obviously help as well. Treatment with testosterone to enhance libido and with sildenafil to improve erection or estrogen to improve lubrication may be considered.

Fatigue

Initial

Efforts to ensure a normal sleep-wake cycle should be made. These include maintenance of a consistent and appropriate bedtime, avoidance of stimulant beverages late in the day, and use of hypnotic agents at bedtime, if needed. For the patient who sleeps well at night but remains easily fatigued during the day, a trial of methylphenidate on arising and at noon may be considered. Loss of initiation due to frontal lobe disease may be perceived as fatigue and occasionally responds to amantadine. For the depressed patient with fatigue, a nonsedating antidepressant should be chosen. Short daytime naps in patients with normal nighttime sleep pattern should not be discouraged.

Rehabilitation

A tailored cardiovascular conditioning program is helpful to maximize the patient's aerobic capacity and physical stamina. Patients with significant physical impairment will benefit from a physical therapist's assistance in designing an adapted conditioning program, which may emphasize use of a stationary bicycle, arm ergometer, and therapeutic pool.

Patients with limiting cardiovascular comorbidities will require the physician's input for heart rate and blood pressure guidelines. Appropriate bracing and use of assistive devices and gait training by an experienced physical therapist can help reduce the energy cost of hemiplegic gait. For some patients, wheelchair propulsion is less fatiguing than walking.

Potential Disease Complications

The spectrum of neurologic and medical complications of stroke in young adults is similar to that in older stroke patients. See Chapter 158.

Potential Treatment Complications

Complications of stroke treatment are similar in young and older adults. They are discussed in Chapter 158.

M32.9 Systemic lupus erythematosus,
unspecified

Definition

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease that is associated with autoantibody production and complement-fixing immune complex deposition. The immune system attack triggers an inflammatory process, resulting in tissue damage. SLE is the prototype of an autoimmune disease that can cause a wide spectrum of clinical presentations and is characterized by remissions and exacerbation. Periods of active illness are sometimes called flares. The course of the disease is unpredictable but can sometimes be triggered by environmental factors, such as ultraviolet light and certain drugs. Although the cause of SLE is not yet fully elucidated, there are known to be a variety of genes that make individuals susceptible to the disease and to its flares. SLE can affect skin, joints, kidneys, lungs, heart, blood vessels, liver, and the nervous system. The disease occurs nine times more often in women than in men, especially in the childbearing years between the ages of 15 and 45 years. The disease can also be found in pediatric and geriatric populations. The prevalence in the general population is approximately 1 in every 2000 persons, but it varies according to race, ethnicity, and socioeconomic background.

The American College of Rheumatology formulated a set of clinical and laboratory findings known as the classi-

fication criteria of SLE in 1985 and subsequently revised them in 1997 (Table 160.1). The classification criteria were designed for investigators recruiting SLE patients into clinical trials, but many clinicians also commonly use them in practice to establish a diagnosis in a given patient.

Symptoms

SLE can cause a variety of symptoms ranging from mild to severe. Patients can present with constitutional symptoms and organ-specific symptoms. Constitutional symptoms include fever, weight loss, and fatigue, which are typically present at some time during the course of the disease in most SLE patients. Mucocutaneous manifestations are important, as shown by the fact that they account for 4 of the 11 classification criteria (see Table 160.1). Skin lesions can be burning, tender, or itching. Rashes such as the classic malar (butterfly) rash and discoid lesions are characteristic. Patients may experience photosensitivity after a period of sun exposure. Photosensitivity is clinically defined as an abnormal response to ultraviolet light. These responses are manifested as exaggerated sunburn reactions and are often associated with systemic symptoms including fever, weakness, fatigue, and joint pain. Photosensitivity seems to correlate strongly with the presence of Ro/SSA antibodies [1]. Oral ulcerations are common and may be painless or asymptomatic. They are commonly on the hard palate and usually indicate active disease. The location and often asymptomatic nature of lupus-related oral ulcerations help differentiate them from non-lupus ulcerations, including aphthous stomatitis, lichen planus, herpes simplex, and drug-related lesions such as thrush due to corticosteroids and mucositis due to methotrexate. Nasal ulcers can also be found during disease activity and are often painful.

Patients may note thin hair, alopecia, or bald spots. Diffuse alopecia is nonspecific and can be caused by many systemic illnesses as well as by drugs such as cyclophosphamide and steroids. Focal bald spots, known as alopecia areata, are almost always due to autoimmune reactions and are characteristic of SLE. Painful red eyes from episcleritis, scleritis, or uveitis can be seen in SLE patients. Visual loss can occur in SLE patients with retinitis, vasculitis, optic neuritis, or thrombosis due to the antiphospholipid antibody syndrome. Some SLE patients experience sicca symptoms of dry eyes and dry mouth due to secondary Sjögren syndrome.

Table 160.1 The 1997 Revised Criteria for the Classification of Systemic Lupus Erythematosus

Criterion	Definition
1. Malar rash	Fixed malar erythema, flat or raised
2. Discoid rash	Erythematous raised patches with keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as an unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulcers, usually painless, observed by physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a. Pleuritis (convincing history of pleuritic pain or rub heard by physician or evidence of pleural effusion) or b. Pericarditis (documented by electrocardiogram, rub, or evidence of pericardial effusion)
7. Renal disorder	a. Persistent proteinuria (>0.5 g/day or $>3+$) or b. Cellular casts of any type
8. Neurologic disorder	a. Seizures (in the absence of other causes) or b. Psychosis (in the absence of other causes)
9. Hematologic disorder	a. Hemolytic anemia or b. Leukopenia ($<4000/\mu\text{L}$ on two or more occasions) or c. Lymphopenia ($<1500/\mu\text{L}$ on two or more occasions) or d. Thrombocytopenia ($<100,000/\mu\text{L}$ in the absence of offending drugs)
10. Immunologic disorder	a. Anti-double-stranded DNA or b. Anti-Sm or c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of immunoglobulin G or M anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any time and in the absence of drugs known to be associated with "drug-induced lupus syndrome"
For identifying patients in clinical studies, a person shall be said to have SLE if any 4 or more of the 11 criteria are present, either serially or simultaneously, during any interval of observation.	

From Hochberg MG. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus [letter]. *Arthritis Rheum* 1997;40:1725.

Patients may present with pleuritic chest pain related to serositis or pulmonary embolism. In addition, SLE patients have a very high incidence of premature atherosclerosis, and myocardial infarctions and strokes are not uncommon in young women with SLE. The authors have seen such events in a number of women in their late teens and 20s.

Epigastric pain in SLE patients can be due to nonsteroidal anti-inflammatory drugs, but the differential diagnosis must include pancreatitis, a life-threatening complication of SLE or of drugs used to treat it, such as azathioprine.

Patients presenting with dependent edema must be evaluated for lupus nephritis, which can cause the nephrotic syndrome. In the case of unilateral leg swelling, deep venous thrombosis needs to be ruled out. The hypercoagulable state in SLE patients is often associated with the antiphospholipid antibody syndrome. Antiphospholipid antibodies, including the lupus anticoagulant, are seen in approximately one fourth of SLE patients. Many remain asymptomatic, but the antibodies are associated with a number of clinical manifestations, including deep venous thrombosis and pulmonary embolism, arterial clots, recurrent spontaneous abortions, and strokes.

Articular symptoms are almost universal in SLE patients. Typical joint involvement in SLE affects the small joints of the hands as well as the wrists, feet, and knees. The joint symptoms are inflammatory in nature; therefore, they tend

to be worse in the morning and are often accompanied by generalized stiffness. Patients generally experience significant joint pain out of proportion to objective physical findings. In patients who have received high doses of corticosteroids, avascular necrosis (osteonecrosis) needs to be in the differential diagnosis of severe joint pain, especially in the hips, knees, and shoulders. Raynaud phenomenon is an additional risk factor for this complication in SLE.

Raynaud phenomenon occurs in at least a third of SLE patients and may be the presenting manifestation. Raynaud phenomenon is caused by episodic vasospasm and ischemia of the extremities in response to cold or emotional stimuli. Typical color change is triphasic from white to blue to red, but many patients do not go through all three phases. Instead, they may just have periods of blanching followed by a return to normal color. In severe cases, digital ulcers may occur and can lead to shortening of the distal phalanx.

Neurologic symptoms, including headaches, numbness, tingling, and weakness, can vary from mild to severe. Strokes are found at an increased incidence in SLE because of both the accelerated atherosclerosis mentioned before and the hypercoagulable state due to associated antiphospholipid antibodies. SLE can also affect the spinal cord with rapidly progressive transverse myelitis, a consideration in any patient with lower extremity neurologic symptoms plus bladder or bowel incontinence.

Proximal muscle weakness involving the upper arms and thighs can be seen in SLE patients as a result of concomitant inflammatory muscle disease. SLE patients are also at risk for steroid myopathy, which is typically much worse in the proximal lower extremities. Patients with myopathy generally present with significant muscle weakness rather than with muscle pain. They have difficulty in using their arms for over-the-shoulder tasks and difficulty in getting up from a chair or a low position as well as using stairs.

Physical Examination

A thorough physical examination is important in evaluating SLE patients, given the nature of their multisystem involvement (Table 160.2). Articular manifestations can present as painful, nonerosive symmetric synovitis. Patients who have had repeated bouts of arthritis in their hands can also develop Jaccoud arthropathy, which is clinically characterized by reversible joint deformities including swan-neck changes, thumb subluxations, ulnar deviation, and boutonnière and hallux valgus deformities along with an absence of articular erosions on plain radiographs (Fig. 160.1). In general, its prevalence is around 5% to 10%.

Table 160.2 Organ Involvement in Systemic Lupus Erythematosus

Mucocutaneous	Facial rashes including malar or butterfly rash, discoid rash, alopecia, photosensitivity, oral ulcerations
Musculoskeletal	Joint pain with or without swelling, morning stiffness, Jaccoud arthropathy, muscle weakness, muscle aches and pain, osteonecrosis
Serosal Cardiovascular	Pleuritis, pericarditis, peritonitis Myocarditis, sterile endocarditis Premature atherosclerosis
Pulmonary	Raynaud phenomenon, digital ulcers Pulmonary hypertension, interstitial lung disease, diffuse alveolar hemorrhage, shrinking lung syndrome, pulmonary embolism
Hematologic	Leukopenia, anemia, thrombocytopenia
Renal Neuropsychiatric	Nephritis, nephrotic syndrome Headaches, seizures, stroke, peripheral neuropathy, cranial neuropathy, transverse myelitis, psychosis, cognitive dysfunction

The skin is second only to the joints as the most frequently affected organ system, and skin disease is the second most common way that SLE initially is manifested clinically [2]. There are three major types of lupus-specific skin disease.

1. The typical malar or butterfly rash involves the cheeks and bridge of the nose. Photosensitive lupus dermatitis is generalized throughout sun-exposed areas.
2. Subacute cutaneous lupus erythematosus. This is a distinct clinical subset of SLE. It is characterized by recurrent, erythematous, photosensitive, nonscarring skin lesions in a characteristic distribution involving the face, trunk, and arms and by mild systemic disease. Anti-Ro/SSA antibodies are found in 63% to 90% of patients with subacute cutaneous lupus erythematosus [3]. The major anti-Ro/SSA response in subacute cutaneous lupus erythematosus is directed against the native 60-kDa Ro protein [4]. Many drugs can induce SLE skin reactions, including photosensitizers such as spironolactone, angiotensin-converting enzyme inhibitors, calcium channel blockers, and hydrochlorothiazide. The skin lesions begin between 4 and 20 months after the initiation of drugs, and the lesions typically improve 6 to 12 weeks after the offending drug is withdrawn [5].
3. Chronic cutaneous lupus erythematosus. The most common form is classic discoid lupus erythematosus (DLE). Clinical features of DLE are induration, scarring, pigment changes, follicular plugging, and hyperkeratosis. Involvement of hair follicles is a prominent clinical feature of DLE lesions. Typical DLE lesions occur most often on the face, scalp, ears, V-neck area of the neck, and extensor aspects of the arms. Scarring alopecia is often observed in patients with scalp involvement. Other forms of chronic cutaneous lupus erythematosus include lupus profundus or panniculitis, mucosal DLE, and chilblain lupus or lupus pernio.

There are generally two common types of alopecia in SLE patients: irreversible scarring alopecia due to persistent DLE activity on the scalp; and the more widespread and often reversible nonscarring focal areas of alopecia that are often present during periods of disease activity. Hair in areas of alopecia is dry and coarse with increased fragility, making it break easily. This is often prominent over the frontal hairline.

FIGURE 160.1 Reversible swan-neck deformities in a patient with SLE (Jaccoud arthropathy).

Because of the nature of painless oral ulceration in SLE, the lesions are often found by a physician on a thorough physical examination, and patients may not recognize them. In patients with inflammatory eye disease such as uveitis or retinitis, a careful examination by an ophthalmologist is needed.

Parotid gland enlargement, several dental cavities, very dry buccal mucosa, or oral thrush can be found in patients with secondary Sjögren syndrome. Oral thrush can also be found in patients who are treated with steroids.

Cardiac examination may reveal a pericardial rub or distant heart sounds in SLE patients with pericardial effusion from pericarditis. Heart murmurs due to noninfectious endocarditis can be detected in SLE patients. Split P_2 , loud P_2 , or right-sided heart heave may suggest pulmonary hypertension, a complication of SLE associated with a high mortality rate. Crackles can also be found in SLE patients from interstitial lung disease, which is treatable if it is detected early.

Splenomegaly is occasionally seen in SLE patients with or without overt hematologic complications of the disease. Focal neurologic deficits and altered mental status can be found in SLE patients with central nervous system involvement including central nervous system vasculitis or stroke from associated antiphospholipid antibody syndrome. The peripheral nervous system can also be involved in SLE patients, including peripheral stocking-glove neuropathies as well as mononeuritis due to vasculitis. In SLE patients with secondary Raynaud phenomenon, abnormal nail fold capillaries can be detected with the presentation of dilated, unorganized capillaries or dropout lesions. Digital ulcers may be evident, and they may be difficult to heal.

Functional Limitations

Because SLE can affect so many systems, disability is common, although it may be reversible once the disease is treated and in remission. However, there are many patients with a complicated course of illness resulting in joint deformity, muscle weakness, or deconditioning after prolonged illness. The functional limitations can be a major issue for these patients even if their acute disease is under control.

All forms of cutaneous lupus have a significant socioeconomic impact within the United States. It has been suggested that cutaneous lupus is the third most common cause of industrial disability from dermatologic disease, with 45% of cutaneous lupus patients experiencing some degree of vocational handicap [6].

Lupus is associated with the gradual development of cognitive dysfunction in a minority of patients. The presence of antiphospholipid antibody, hypertension, and stroke are key variables associated with cognitive impairment [7].

Fatigue is one of the most common complaints and can be debilitating. The cause of fatigue is most likely multifactorial. Many potential causes include cytokines associated with active inflammation, deconditioning from prolonged illness, sleep disturbances, sedentary lifestyle, anemia, hypothyroidism, depression, stress, and medications such as steroids and beta blockers. Fatigue symptoms from SLE may respond to steroids or antimalarial treatment in some cases. Fatigue does not always correlate with other evidence of disease activity. There is a strong association between fatigue and decreased exercise tolerance. In one study of

women with SLE, the oxygen consumption kinetics was prolonged and the prolongation was accompanied by an increase in oxygen deficit. This may explain the performance fatigability in this group of patients [8].

Diagnostic Studies

The classification criteria (see Table 160.1) can be a useful guide in making the diagnosis. The diagnosis of SLE is made by the American College of Rheumatology criteria if four or more of the manifestations are present, either serially or simultaneously, during any interval of observation.

Specific laboratory findings include antinuclear antibodies (ANA), antiphospholipid antibodies, and complement levels (Table 160.3). The most characteristic laboratory finding in SLE is the presence of ANA, and a negative ANA titer makes a diagnosis of lupus extremely unlikely. Titers are typically 1:160 or higher. Whereas the ANA titer is very sensitive, it is not very specific; the false-positive rate in healthy controls varies from approximately 30% with ANA titers of 1:40 (high sensitivity, low specificity) to as little as 3% with ANA titers of 1:320 (low sensitivity, high specificity) [9]. On the other hand, anti-double-stranded DNA and anti-Smith antibodies are highly specific for SLE. Anti-Ro/SSA and anti-RNP antibodies can also be found in SLE patients. Complement levels, usually C3 and C4, tend to fall during periods of active disease, especially if there is renal involvement. If patients have venous or arterial thrombosis or recurrent second-trimester spontaneous abortions, tests for the lupus anticoagulant should be performed.

Nonspecific laboratory findings include leukopenia, anemia, and thrombocytopenia, which are present in many patients during periods of active disease. Anemia can often be due to chronic disease or iron deficiency. Less commonly, it can be Coombs-positive hemolytic anemia. Proteinuria and hematuria with an active urinary sediment including cellular or granular casts are typical in SLE patients with nephritis. Kidney function can be compromised, as evidenced by elevated creatinine concentration and abnormal electrolyte levels. Creatine kinase concentration can be elevated in SLE patients with muscle involvement. Inflammatory markers, including erythrocyte sedimentation rate and C-reactive protein level, are usually elevated in SLE patients with active disease.

Imaging testing is generally obtained in SLE patients with signs or symptoms concerning for organ-specific manifestations. Plain radiographs of involved joints may show evidence

Table 160.3 Laboratory Testing in Systemic Lupus Erythematosus

Autoantibody testing, including antinuclear antibody, antiphospholipid antibody, anti-double-stranded DNA antibody, and anti-Smith antibody
Complete blood count and differential counts

suggestive of inflammatory arthritis, such as periarticular osteopenia. Renal ultrasonography is useful to assess kidney size in patients with renal insufficiency, and magnetic resonance angiography is used to assess renal vein thrombosis in patients with the nephrotic syndrome. Chest radiography may be helpful in SLE patients with cough, chest pain, or shortness of breath as lupus can cause both interstitial and pleural disease. Echocardiography is obtained in cases of suspected pericardial involvement or cardiac disease as well as to assess pulmonary artery pressure. Computed tomography of the chest is useful in SLE patients with interstitial lung disease, and a computed tomography scan of the abdomen may be considered in the evaluation of abdominal pain, especially when pancreatitis is suspected. Magnetic resonance imaging of the brain or spinal cord can give evidence that suggests a cause of focal neurologic deficits or cognitive dysfunction in SLE patients. In vasculitis, angiography may be valuable. When osteonecrosis is suspected, magnetic resonance imaging of joints is helpful. Musculoskeletal ultrasonography has been reported as a useful tool for assessment and defining of complications of joint and tendon in SLE patients [10].

In some cases, in addition to clinical and laboratory findings, the diagnosis of SLE is made by surgical pathology, such as skin or kidney biopsy showing characteristics strongly suggestive of SLE. Interface dermatitis with immune complexes at the dermal-epidermal junction is characteristic of lupus skin biopsy specimens. Immunofluorescent staining of kidney biopsy specimens from SLE patients commonly reveals “full-house staining” of immunoglobulin G, immunoglobulin M, immunoglobulin A, C3, and C1q.

Treatment

Treatment of SLE must be personalized for each patient by the extent of organ involvement. The purpose of treatment focuses on inducing remission, maintaining normal function, and preventing damage. Corticosteroid therapy is used in SLE at various dosages according to the severity of the disease. With serious organ involvement, such as kidney, lung, or central nervous system disease, cyclophosphamide therapy is commonly given along with corticosteroids. Other agents, such as azathioprine, mycophenolate mofetil, leflunomide, rituximab, abatacept, intravenous immune globulin, and interferon alfa blockade, have been used in SLE.

Treatment of cutaneous lupus includes nonpharmacologic and pharmacologic approaches. Nonpharmacologic treatments are photoprotection from both ultraviolet A and B rays, smoking cessation, and avoidance of trauma to the skin (such as tattoos or tanning beds). Pharmacologic treatments include topical and systemic medications. Topical corticosteroids, intralesional corticosteroids, topical calcineurin inhibitors, and topical retinoids have been recommended in cutaneous lupus. The most common systemic medication used in cutaneous lupus is hydroxychloroquine. The combination of hydroxychloroquine and quinacrine or of chloroquine and quinacrine is an alternative when patients do not respond well to hydroxychloroquine alone. Other medications, such as methotrexate, oral retinoids, dapsone, mycophenolate mofetil, and thalidomide, have been used in cutaneous lupus.

The treatment of Jaccoud arthropathy is conservative. Medical treatment is recommended with nonsteroidal anti-inflammatory drugs, low-dose corticosteroids, antimalarials, or methotrexate.

Hydroxychloroquine is effective for the amelioration of joint symptoms and for the prevention of clinical lupus relapse [11]. The dose is weight based at less than 6.5 mg/kg/day, which is generally 200 to 400 mg/day. The recommendations on eye screening for hydroxychloroquine or chloroquine retinopathy have been revised by the American Academy of Ophthalmology [12]. It is strongly recommended that all patients beginning hydroxychloroquine or chloroquine therapy have a baseline examination within the first year of starting the drug to document any complicating ocular conditions and to establish a record of the fundus appearance and functional status. Annual screening should be performed after 5 years of drug use in all patients. In patients with maculopathy or risk factors such as liver or renal disease or advanced age, annual screening should be performed from the initiation of therapy.

Belimumab is the first biologic agent approved for the treatment of SLE by the U.S. Food and Drug Administration. It is the first drug approved in 55 years after hydroxychloroquine and corticosteroids were approved in 1955 and aspirin was approved in 1948. Belimumab is a fully humanized recombinant immunoglobulin G1 λ monoclonal antibody that inhibits the binding of soluble B-lymphocyte stimulator to B cells and hence prevents the survival and differentiation of selected B-cell subsets. It is for the treatment of adult patients with active, autoantibody-positive SLE with a high degree of disease activity despite receiving standard therapy. It is well tolerated and appears to be efficacious in the treatment of SLE, although it is not approved for treatment of lupus nephritis or neuropsychiatric lupus [13,14].

Rehabilitation

In lupus patients with fatigue, supervised graded exercise programs show an improvement in aerobic capacity, quality of life, and depression [15,16]. The beneficial effects disappeared on stopping of exercise.

In some early cases of avascular necrosis, reduced weight bearing, limitation of activities, or use of crutches can occasionally slow the damage and permit natural healing [17]. Range of motion exercises are helpful for maintaining joint function.

In SLE patients with pulmonary hypertension, interstitial lung disease, or cardiac disease, cardiopulmonary rehabilitation is important once the patients are clinically stable.

Procedures

In lupus patients with active synovitis, tendinitis, or bursitis, local corticosteroid injections are helpful and can sometimes be used in lieu of systemic corticosteroids.

Osteonecrosis or avascular necrosis of the hip is a progressive disease. The prevention of femoral head collapse is highly desirable in the young lupus patient. In early-stage disease, before femoral head collapse (Ficat and Arlet stages I to III), core decompression of the femoral head is currently the most widely used procedure to try to relieve intraosseous pressure in the femoral head and to restore blood supply (Table 160.4).

Table 160.4 Avascular Necrosis of Femoral Head Classification: Ficat and Arlet

Stage 0: preclinical or preradiologic	Normal findings on a plain radiograph in an asymptomatic patient with a positive diagnosis in the contralateral hip The magnetic resonance image shows a double-line sign, consistent with a necrotic process.
Stage I: preradiologic	Normal findings on radiographs and abnormal findings on magnetic resonance imaging or bone scintigraphy
Stage II: reparative stage Stage IIA	Radiographic changes are demineralization, patchy sclerosis in the superolateral aspect of the femoral head, and small cysts within the femoral head
Stage IIB	A transition phase characterized by the presence of the crescent sign, seen as a linear subcortical lucency situated immediately beneath the subcortical bone, representing a fracture line
Stage III Stage IV	Flattened or collapsed femoral head Progressive degenerative joint disease with severe collapse and destruction of the femoral head, joint space narrowing, and osteophyte and subchondral cyst formation

Surgery

Lupus patients are prone to spontaneous tendon ruptures, including the Achilles tendon, the patellar tendon, and the long tendons of the hands. Early surgical repair is usually the treatment of choice.

In severe avascular necrosis of hips, knees, or shoulders, arthroplasty is required. Studies of the natural history of the disease suggest that femoral head collapse occurs within 2 to 3 years of the first symptoms, and at that stage arthroplasty is the most reliable treatment option. The outcome of hip arthroplasty showed an overall survival probability of 94.6% at 5 years and of 81.8% at 9 years with minimal perioperative morbidity [18]. Besides standard total hip arthroplasty, bipolar hemiarthroplasty, limited femoral resurfacing, and metal-on-metal resurfacing are alternatives. Because of the incidence of gluteal and groin pain and migration, total hip arthroplasty is a better procedure than bipolar hemiarthroplasty for patients with Ficat stage III osteonecrosis of the femoral head [19].

Potential Disease Complications

Jaccoud Arthropathy

This arthropathy may compromise hand function and is also a risk factor for tendon rupture [20].

Increased Risk of Infection

Although SLE patients are often leukopenic, they typically can mobilize white blood cells normally, so that SLE patients not receiving immunosuppressive therapy do not have

a significantly increased risk of infection. However, patients receiving corticosteroids and other immunosuppressives are at increased risk of opportunistic infections. In anticipation of the need for immunosuppression, SLE patients should receive appropriate immunizations including pneumococcal and influenza vaccines. Live vaccines, such as the herpes zoster vaccine, should not be given to patients receiving immunosuppressive agents.

Hypertension

Hypertension can be seen in SLE patients with lupus nephritis and should be treated aggressively, preferably to 130/80 mm Hg or lower.

Premature Atherosclerosis

It has been recognized that premature coronary artery disease is a major cause of illness and death in SLE patients. Coronary atherosclerosis is much more prevalent among patients with lupus than in the general population and cannot be predicted by the measurement of traditional risk factors or markers of disease activity [21]. Many factors influence this process, including dysfunctional immune regulation, inflammation, traditional risk factors, defective endothelial cell function, and vascular repair as well the therapeutic used to treat the underlying autoimmune disease. SLE-specific factors including disease activity, disease duration, damage, and proinflammatory high-density lipoprotein could also contribute to increased atherosclerotic risk [22].

Potential Treatment Complications

The potential side effects and toxicities of hydroxychloroquine are retinal toxicity, hyperpigmented skin lesions, myopathy with vacuolization on muscle biopsy, and cardiomyopathy (Table 160.5).

Table 160.5 Potential Treatment Complications

Treatment	Complication
Nonsteroidal anti-inflammatory drugs	Dyspepsia, peptic ulcer, gastrointestinal bleeding, platelet dysfunction, renal insufficiency, hepatotoxicity, aseptic meningitis
Glucocorticoids	Cushingoid appearance, weight gain, fluid retention, acne, hypertension, diabetes, cataracts, glaucoma, avascular necrosis, osteoporosis, impaired wound healing, increased susceptibility to infection
Antimalarials	Retinopathy, abnormal skin pigmentation, neuromyopathy, cardiomyopathy
Cyclophosphamide	Myelosuppression, hemorrhagic cystitis, bladder cancer, infertility, alopecia
Azathioprine	Myelosuppression, hepatotoxicity, pancreatitis
Methotrexate	Myelosuppression, hepatotoxicity, mucositis, alopecia, pneumonitis
Mycophenolate mofetil	Myelosuppression, dyspepsia, diarrhea

Definition

Transverse myelitis is a focal inflammation across the spinal cord along one or more levels. This inflammation can cause damage to the ensheathing nerve cell fiber myelin, with resultant nervous system dysfunction [1]. The diagnosis may incorporate the terms *acute*, meaning arising suddenly and intensely, and *idiopathic*, in which no specific bacterial, viral, or other obvious inflammatory cause can be found. Other descriptors include *acute partial*, *acute complete*, and *longitudinally extensive*. Few population-based studies are available, and comparative or meta-analysis of the literature is difficult because of the different presentations of transverse myelitis being reported. It appears, however, that

acute transverse myelitis is rare, with only 1400 new cases annually in the United States, or 1 to 4 cases per million population per year [1,2].

An older study from 1993 in the United States on acute or subacute noncompressive myelopathy showed these cases to be 45% parainfectious, 21% multiple sclerosis, 12% spinal cord ischemia, and 21% idiopathic [3]. With the availability of improved diagnostic tools, possible changes in disease patterns, and longer follow-up, the etiology of transverse myelitis may be clearer. A 2012 study from France on acute partial transverse myelitis with a median follow-up period of 104.8 months reported the etiology of cases as 62% multiple sclerosis, 1% postinfectious myelitis, 1% neuromyelitis optica, 1% Sjögren syndrome, and 34% undetermined (i.e., idiopathic) [4]. However, another French multicenter retrospective study applying the Transverse Myelitis Consortium Working Group criteria [2] for acute transverse myelitis to 288 subjects was more evenly spread. It reported the etiology as 20.5% systemic disease (systemic lupus erythematosus, Sjögren syndrome, antiphospholipid syndrome), 18.8% spinal cord infarct, 10.8% multiple sclerosis, 17.3% infectious or parainfectious, 17% neuromyelitis optica, and 15.6% idiopathic acute transverse myelitis [5].

There is a female predominance of 60% to 75% [4–9] and a bimodal age distribution. Patients having transverse myelitis related to multiple sclerosis, postinfectious transverse myelitis, or idiopathic transverse myelitis are younger, whereas those with transverse myelitis related to spinal cord infarcts or delayed radiation effects are older [4,6,8,10]. Transverse myelitis may recur, with reported rates ranging from 17.5% [9] to 61% [8], and relapse appears to be more common with acute partial transverse myelitis [11].

According to one magnetic resonance imaging (MRI) study, idiopathic acute transverse myelitis most commonly affects the cervical region (60%), followed by the thoracic region (33%) [5]. The onset of transverse myelitis can be acute (within hours or days) or subacute (between 1 and 4 weeks) [1,3]. The period from onset to complete weakness in idiopathic transverse myelitis has been reported to range from 10 hours to 28 days, with a mean of 5 days [10]. Subacute presentations, progressing over days to weeks and ascending, are associated with a good to fair prognosis. Acute and catastrophic presentations with back pain have a poorer outcome [12].

Symptoms

Patients with transverse myelitis may present in the ambulatory clinic or hospital setting with complaints of weakness

of the arms and legs, pain, sensory impairments, or difficulties with the bowel and bladder. Weakness may affect the lower limbs or all four limbs with varying severity. Sensory complaints may include hypersensitivity, numbness, tingling, coldness, or burning. Pain is a common symptom in a third to one half of patients and may be localized or shooting in character. Bowel frequency or constipation may occur, and bladder symptoms include increased frequency, retention, and incontinence [1,10].

The history may reveal symptoms of recent infection, immunocompromised or autoimmune condition, space-occupying lesion, demyelinating disease, travel, vaccination, trauma, sexual exposure, animal bites, and insect or tick bites. A careful review may yield systemic symptoms, including the upper respiratory tract with cough and difficulty in breathing, chest pain, rashes, joint aches, muscle pain, vision changes, nausea, diarrhea, constipation, and problems with urinary function. Particular attention should be paid to details pointing toward potentially treatable or reversible conditions responsive to antimicrobials or surgical decompression.

Any history of invasive spinal intervention for pain management should be explored. Cases of acute paraplegia with sensory, bowel, and bladder dysfunction have been reported after epidural steroid injections and lumbosacral nerve root blocks. Inadvertent direct cord injury may occur, or a vascular injury resulting in cord infarction may be the cause [13–15]. Damage to an abnormally low artery of Adamkiewicz as it travels with the nerve root through the neural foramen has been postulated. This dominant radiculomedullary artery arises between T9 and L2 levels in 85% of people, but it may arise from the lower lumbar region to as low as S1 [15]. There has also been a report of transverse myelitis resulting from the infected catheter tip of an intrathecal morphine pump for chronic pain [12].

Physical Examination

The physical examination follows a thorough history taking and will focus on the manifestations and findings relating to myelopathy, such as motor weakness, changes in sensation (pinprick, light touch, vibration, position sense, or temperature), tone, muscle stretch reflexes, coordination, and bowel and bladder functioning. Changes affecting the brain, such as cognitive dysfunction and cranial nerve and visual abnormalities, are generally not seen with idiopathic transverse myelitis and suggest other diagnoses.

Temperature elevation, tachycardia, and tachypnea may indicate an infectious etiology. Infections and autoimmune conditions that cause acute inflammation of the spinal cord may also be manifested in the other body systems. The respiratory, cardiovascular, gastrointestinal, and genitourinary tracts as well as the musculoskeletal and integumentary systems should be assessed accordingly. The findings may assist in determining the level of spinal involvement, guide diagnostic testing for the myelitis, and help rule out other diagnoses.

Functional Limitations

The physiatrist is likely to encounter the patient as a consultation or referral for rehabilitation assessment and

management or for specific problems, such as spasticity and pain intervention. As with other spinal cord injuries, the functional limitations in transverse myelitis usually depend on the level or levels of injury and the muscles that are affected or continue to be innervated normally. Debilitation and deconditioning from associated illnesses and prolonged recumbence will also affect function secondarily.

Recovery is often related to the clinical presentation and may or may not be complete. In general, one third of patients with acute transverse myelitis make a good recovery, another third have fair recovery, and the rest either fail to improve or die [5,7,10,16]. In idiopathic transverse myelitis treated with methylprednisolone, by use of the Medical Research Council (MRC) scale for muscle strength (5, normal; 0, no movement is observed), 37.5% were reported to have complete recovery or minimal residual deficit (MRC 5-4), 43% had partial recovery (MRC 3), and 19.4% had severe disability or absent recovery (MRC 0-2). Factors associated with poor outcomes include severe initial symptoms with spinal shock, delayed presentation to the hospital after maximum deficits have already occurred, development of syringomyelia, and extensive MRI lesions [5,10]. If no recovery has occurred by 1 to 3 months, complete recovery is less likely [3,12].

The following functional capability review according to spinal level may be influenced by whether the cord injury is unilateral or bilateral and the degree of completeness. A patient with only C4 innervation preserved and loss of function distally may or may not have respiratory difficulties but will be dependent for most self-care activities. Using appropriate technology and devices, whether they are customized or commercially available, the patient may be able to control the immediate home environment, summon assistance, and mobilize in an electric wheelchair with a chin control or a sip-and-puff interface. Devices that can be controlled by moving and positioning the head, cheek, or tongue and by infrared-sensitive or voice-activated mechanisms include door openers and various electronic devices such as the television and personal computer.

A patient with C5 level may be able to self-feed and groom with equipment such as a glove with universal cuff allowing attachment of tools (e.g., fork, spoon, or comb). The patient can independently use a powered wheelchair and propel a lightweight manual wheelchair with rim projections ("quad knobs") for limited distances over level ground. C6 innervation allows independence with upper extremity dressing, bathing with equipment, and functional use of a manual wheelchair indoors. The patient with superior balance and motor control could potentially perform independent or supervised transfers with a sliding board, self-catheterize with appropriate aids, and drive a specially adapted automatic transmission vehicle with powered steering, hand-controlled accelerator and brake. A C7 level allows independence in all self-care activities with equipment and independent transfers because of preserved ability to push off with the elbow extensors, and the patient may be able to live alone. A patient with C8 and T1 innervation will have improved manual dexterity and strength for self-care, is independent with a manual wheelchair, and should be able to self-catheterize.

The patient with preservation of upper thoracic innervation has a degree of trunk control that increases stability during use and propulsion of a manual wheelchair. It also

adds to ease and independence with bladder and bowel self-management. With bracing of the hips, knees, and ankles (knee-ankle-foot orthoses), minimal ambulation can be attempted, although this would be more for encouragement and exercise purposes than truly functional. Independent ambulation even with bracing and bilateral axillary or forearm crutches is usually not realistic unless the patient has preservation of some upper lumbar innervation. Further preservation of lumbar and sacral innervation will increase ease of ambulation with better trunk and pelvic control. There have been developments in exoskeleton systems to assist standing and ambulation, such as the ReWalk (Argo Medical Technologies Inc., Marlborough, Mass) and Ekso (Ekso Bionics, Richmond, Calif), although these are currently still limited by the individual patient's abilities, terrain, and need for safety supervision. The patient with incomplete spinal injury is less predictable, and functional abilities will largely depend on the degree and nature of neurologic preservation.

Diagnostic Studies

With increasingly greater resolution, T1 versus T2 weighting, and other techniques to enhance and to suppress the appearance of tissues of different densities, the best tool when transverse myelitis is suspected is MRI. MRI not only allows visualization of the lesion but also helps rule out potentially treatable causes, such as tumor, abscess, and other lesions causing compressive myelopathy. Contrast material can be given to highlight lesions [17], and myelography may be considered if MRI is not available.

Although it is not definitive, there are MRI features that help differentiate transverse myelitis from other disorders, such as multiple sclerosis (Figs. 161.1 and 161.2). Transverse myelitis is more likely to have high signal intensity on T2-weighted images extending longitudinally over more segments [17,18]. The number of segments involved may be 1 or 2, to as many as 11. The entire cord or sometimes only the medulla may be affected [17–20]. In transverse myelitis, the lesion appears more likely to affect the central region of the cord and to involve more than two thirds of the cord diameter.

In multiple sclerosis, the lesion appears more peripheral and generally involves less than half of the diameter of the cord [17]. The lesion in transverse myelitis is more likely to resemble a spinal cord tumor, and biopsy may even be mistakenly performed [17,18]. MRI of the brain with contrast enhancement is often performed to help determine whether the patient's condition is a prelude to multiple sclerosis rather than “idiopathic” transverse myelitis. In idiopathic partial transverse myelitis, a study that does not show brain lesions translates to the likelihood of evolving multiple sclerosis at 15% to 44%. When brain lesions such as white matter plaques (especially periventricular) are seen, the chance for development of multiple sclerosis increases to 44% to 93% [21]. Asymmetric motor or sensory symptoms and absence of peripheral nervous system involvement at presentation suggest acute myelopathic multiple sclerosis, whereas symmetric symptoms and neurophysiologic evidence of peripheral nervous system involvement suggest acute transverse myelitis [22,23].

Immunoglobulin G antibodies may be useful for determining neuromyelitis optica as the etiology in patients with acute complete transverse myelitis. Longitudinally exten-

FIGURE 161.1 Myelitis: T2-weighted magnetic resonance image of the sagittal spine with fusiform lesion at C7-T1 (arrow).

FIGURE 161.2 Myelitis: T2-weighted magnetic resonance image of the axial cervical spine showing lesion across most of the spinal cord (arrow).

sive transverse myelitis spanning three or more vertebral segments is an important feature of neuromyelitis optica, and detection of anti-aquaporin 4–specific antibodies (anti-AQP4) is useful to determine both increased risk for recurrence and conversion to neuromyelitis optica [11,24].

Other tests include blood counts and chemistry; tests for autoimmune conditions, such as antinuclear antibodies, anti-double-stranded DNA antibodies, anti-Sm antibodies, and erythrocyte sedimentation rate; SS-A antibody for Sjögren disease; immunoglobulin levels; and VDRL test.

Vitamin B₁₂ levels may be tested, and *Mycoplasma pneumoniae* or *Mycobacterium* cultures may be performed. Lyme titers and titers for various viruses including human immunodeficiency virus, West Nile virus, poliovirus, hepatitis virus, Epstein-Barr virus, cytomegalovirus, and enteric cytopathic human orphan virus may be elevated.

A lumbar puncture allows the assessment of central nervous system pressure as well as obtains cerebrospinal fluid for cell count, determination of protein and glucose concentrations, measurement of immunoglobulins, and protein electrophoresis. Oligoclonal bands detected in the cerebrospinal fluid are useful in making a diagnosis. In one report, they were present in three of five patients with multiple sclerosis-associated transverse myelitis but in none of four patients with parainfectious transverse myelitis [3]. Vascular flow studies or clotting parameters may be needed if spinal hematoma, thrombosis, or vasculitis is suspected.

Electrodiagnostic studies, including somatosensory and motor evoked potentials, may be useful for both diagnostic purposes and monitoring of treatment progress [25]. A urinary evaluation may include cystography, voiding cystourethrography, and cystoscopy. Baseline renal ultrasound and urodynamic evaluation have been recommended because of the very high rates of persistent long-term bladder dysfunction [26,27]. Bowel evaluation may require radiography, computed tomography, MRI, or colonoscopy to rule out obstruction.

In 2002, the Transverse Myelitis Consortium Working Group proposed the criteria in Table 161.1 for the diagnosis of idiopathic acute transverse myelitis [2].

A comparison by de Seze [6] of the clinical findings, MRI results, laboratory profiles, and outcomes of patients with acute myelopathy according to etiology is presented in Table 161.2.

Table 161.1 Criteria for the Diagnosis of Idiopathic Acute Transverse Myelitis

Inclusion Criteria	Exclusion Criteria
<ul style="list-style-type: none"> • Development of sensory, motor, or autonomic dysfunction attributable to the spinal cord • Bilateral signs or symptoms (although not necessarily symmetric) • Clearly defined sensory level • Exclusion of extra-axial compressive etiology by neuroimaging (MRI or myelography; CT of spine not adequate) • Inflammation within the spinal cord demonstrated by CSF pleocytosis or elevated IgG index or gadolinium enhancement. If no inflammatory criterion is met at symptom onset, repeated MRI and lumbar puncture evaluation between 2 and 7 days after symptom onset meet criteria. • Progression to nadir between 4 hours and 21 days after the onset of symptoms (if patient awakens with symptoms, symptoms must become more pronounced from point of awakening) 	<ul style="list-style-type: none"> • History of previous radiation to the spine within the last 10 years • Clear arterial distribution clinical deficit consistent with thrombosis of the anterior spinal artery • Abnormal flow voids on the surface of the spinal cord consistent with AVM • Serologic or clinical evidence of connective tissue disease (e.g., sarcoidosis, Behçet disease, Sjögren syndrome, SLE, mixed connective tissue disorder)* • CNS manifestations of syphilis, Lyme disease, HIV, HTLV-1, mycoplasma, other viral infection (e.g., HSV-1, HSV-2, VZV, EBV, CMV, HHV-6, enteroviruses)* • Brain MRI abnormalities suggestive of multiple sclerosis* • History of clinically apparent optic neuritis*

*Do not exclude disease-associated acute transverse myelitis.

AVM, arteriovenous malformation; CMV, cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EBV, Epstein-Barr virus; HSV, herpes simplex virus; IgG, immunoglobulin G; HHV, human herpes virus; HIV, human immunodeficiency virus; HTLV-1, human T-lymphotropic virus 1; MRI, magnetic resonance imaging; SLE, systemic lupus erythematosus; VZV, varicella-zoster virus.

Modified from Transverse Myelitis Consortium Working Group. Proposed diagnostic criteria and nosology of acute transverse myelitis. *Neurology* 2002;59:499-505.

Table 161.2 Comparison of Findings Based on Etiology [6]

Etiology	Findings	Prognosis
Multiple sclerosis	MRI: lesions small, localized in lateral or posterior cord, more cervical CSF: oligoclonal bands	Clinical outcome good but relapse in 47% at mean of 21 months
Systemic disease (SLE, Sjögren syndrome)	Severe motor and sphincter problems MRI in SLE: large and centromedullary lesions CSF: > 30 cells	Clinical outcome poor
Spinal cord infarct	No clear diagnostic criteria acutely; > 50 years old; severe motor and sphincter problems MRI: isolated centromedullary lesions CSF: absent or low cells, no oligoclonal bands	Outcome poor or fair in 91% of cases
Parainfectious myelopathy	Severe motor and sphincter problems MRI: large centromedullary lesions, cervicodorsal frequently CSF: > 30 cells, no oligoclonal bands Serologic confirmation rarely obtained	Clinical outcome good
Delayed radiation myelopathy	History of irradiation; delay can exceed 10 years MRI: high-intensity cord signals with focal swelling, follow-up cord atrophy CSF: normal	Clinical outcome good in early (10-16 weeks after) radiation myelopathy, poor in delayed
Unknown etiology	Long-term follow-up produces diagnosis in 50% of cases	

CSF, cerebrospinal fluid; MRI, magnetic resonance imaging; SLE, systemic lupus erythematosus.

Differential Diagnosis**[1,3,8,13–17,19–21,28–30]**

Demyelinating disease
Multiple sclerosis
Neuromyelitis optica (Devic disease)

POSTINFECTIOUS OR PARAINFECTIOUS

Viral: Epstein-Barr virus, herpes simplex, varicella-zoster, cytomegalovirus, human immunodeficiency virus, enteroviruses (poliovirus, coxsackievirus, enteric cytopathic human orphan virus, echovirus), mumps, adenovirus, rubella, measles, angiotropic large-cell lymphoma, leukemia virus, influenza, rabies, West Nile virus
Bacterial: Lyme borreliosis, syphilis, tuberculosis, pneumonia (*Mycoplasma pneumoniae*), cat-scratch disease (*Bartonella henselae*), histoplasmosis

AUTOIMMUNE

Systemic lupus erythematosus
Sjögren syndrome
Sarcoidosis
Behçet disease
Mixed connective tissue disease

SPINAL CORD ISCHEMIA OR INJURY

Space-occupying lesions: tumors, herniated nucleus pulposus, spinal abscess, hematoma, spinal stenosis
Vascular: atherosclerosis, thrombosis of spinal arteries, arteriovenous malformations, vasculitis in heroin abuse, iatrogenic

OTHERS

Idiopathic
Post-vaccination (measles, mumps, chickenpox, rabies)
Paraneoplastic syndrome

Treatment**Initial**

Although the physiatrist may manage stable long-standing transverse myelitis on an outpatient basis, hospitalization may be necessary to monitor vital signs, to manage respiratory status and bowel or bladder complications, and to carry out diagnostic investigations, particularly during the acute presentation [26,31]. Abnormalities of the vital signs, such as tachypnea or tachycardia, may suggest impaired oxygenation or blood flow that may need to be managed urgently. The ability to provide antiviral agents, antibacterial agents, and surgical decompression may also be critical, depending on whether a specific cause has been identified.

Various medications have been tried for idiopathic transverse myelitis without clear success in changing the course. Intravenous methylprednisolone has been advocated to prevent further damage to the spinal cord as a result of swelling [19,20]. During the acute phase, it may lead to faster recovery and less disability, and it is well tolerated according to several small observational studies [21]. Cyclophosphamide exerts an immunosuppressive and immunomodulatory effect through suppression of cell-mediated and humoral immunity (i.e., on the T cells and B cells) [21]. Cyclophosphamide in combination with methylprednisolone has some success on lupus-related lesions [20,29]. However, there appears to be an absence of any beneficial

effect of immunosuppressive drugs (cyclophosphamide, azathioprine, intravenous immune globulin) in patients with idiopathic acute transverse myelitis [5]. Plasma exchange to remove autoreactive antibodies and other toxic molecules from plasma can be effective, especially within 20 days of onset, to increase chances of a good clinical response [21].

Rehabilitation

Rehabilitation is a crucial component of the treatment for any spinal cord injury, and the more affected or severe cases of transverse myelitis will require a comprehensive multidisciplinary rehabilitation program led by a physiatrist. Physical and occupational therapists on the team can work with patients on strengthening, endurance, balance, coordination, joint range of motion, reconditioning, mobility, and independence with activities of daily living. If pain is present, appropriate medications and heat, cold, and electrical modalities including transcutaneous electrical stimulation may be helpful.

An orthotist can improve mobility with bracing devices such as an ankle-foot orthosis or knee-ankle-foot orthosis. An assessment for appropriate equipment, such as wheelchair, and other assistive and walking devices, is needed. Education of the patient and family about the disease, resultant impairments, potential complications, and plans and prognosis for rehabilitation is important. The psychological state of the patient should not be neglected, and there should be monitoring for depression. Discharge planning needs and issues potentially affecting the patient's community reintegration should be assessed.

Transverse myelitis may or may not be a transient condition. Recovery may occur, and it is important to minimize the effects of even temporary denervation. All muscles and joints should be kept as active as possible, and having the joints go through a full range of motion daily will help prevent contractures. Passive and active exercises at all times and electrical stimulation are methods to keep muscles as flexible and strong as possible. If respiration is compromised, exercises for muscles of inspiration may be started, glossopharyngeal breathing may need to be taught, and electrical stimulation of the diaphragm may need to be considered [31].

Spasticity is a possible complication as with other upper motor neuron lesions. Regular stretching and use of antispasticity medications, such as baclofen, diazepam, and tizanidine, can minimize and decrease development of joint contractures. An antiepileptic drug (e.g., gabapentin) can also have a degree of antispasticity effect. Checking the skin thoroughly on a daily basis can potentially avoid skin breakdown and associated infections. Insensate areas of high pressure should be relieved with special cushions and mattresses, such as egg crate foam and alternating pressure overlays, and pressure-relieving ankle-foot orthoses may be helpful.

Bladder and bowel programs should be started immediately because a neglected neurogenic bowel or bladder may lead to stool obstruction or kidney damage. An indwelling catheter can initially be used for bladder drainage, but intermittent catheterization, independently or otherwise, is commonly instituted whenever possible. Long-term follow-up of 2 to 10 years in pediatric patients with transverse myelitis has shown that residual bladder dysfunction is common even with improvement of paraparesis and lack of urologic

symptoms. In one study, 86% had persistent bladder dysfunction and 77% had persistent bowel dysfunction [27].

A bowel program includes adequate fluids, proper diet, activity, and scheduled bowel movements. Upper motor neuron bowels may need a stool softener (e.g., docusate), osmotic laxative (lactulose), or stimulant laxative (senna or bisacodyl) for evacuation. Digital stimulation of the rectum is often effective and needs to be taught. With areflexic lower motor neuron bowels, use of bulk laxatives like psyllium or methylcellulose to obtain formed stools may help during digital manual evacuation. Bowel training is often started on a daily basis in the hospital, but the frequency can be extended to every 2 or 3 days once an individual returns home.

Individuals who require assistive devices for mobility must be trained in use of a wheelchair, walker, crutches, or cane, including maneuvering over steps and curbs. If transfers and ambulation require assistance, training of family members or assistants becomes crucial.

For patients with transverse myelitis at the cervical level, various types of equipment and temporary or permanent orthoses can be provided to help with self-care activities. Proper bathroom equipment and modifications, such as a tub bench, commode, hand-held shower, raised toilet seat, and grab bars, may make the difference between dependence and independence. Selection of appropriate aids is essential to maximize function, and many are expensive. Timing of these purchases may need to be carefully considered in this possibly transient condition. Despite a reasonable prognosis for eventual recovery, inaction may result in secondary complications, and it is important to keep an individual as functionally independent and active as possible throughout the entire recovery period.

Procedures

Procedures in transverse myelitis are determined by which systems are affected by the spinal cord injury. Renal ultrasound and urodynamic evaluations are relatively routine procedures for these patients to assess and monitor bladder dysfunction. Intramuscular botulinum toxin injections or alcohol or phenol nerve and motor point blocks may be needed for spastic limb muscles. An intrathecal baclofen pump may be effective in intractable cases and allows much smaller doses and concomitantly fewer side effects. Other procedures include implantation of diaphragmatic electrodes (phrenic nerve stimulation) when respiratory muscles have been affected. Some patients receive functional electrical stimulation systems to help maintain fitness or to increase hand and ambulatory function. Although not routinely done presently, anterior sacral root stimulation may be effective for bladder management.

Surgery

There is no specific curative surgical procedure for idiopathic transverse myelitis. However, when there are compressive abnormalities such as abscess, herniated nucleus pulposus, spinal stenosis, and tumor, surgery may be needed as soon as possible to relieve pressure on the spinal cord. Timely management of compressive lesions may reverse neurologic injury to the cord or at the least stop further injury.

Secondary complications from spinal cord dysfunction may require surgical intervention. These include skin

breakdown, accidental injury including fractures from lack of sensation in muscles and joints, development of kidney stones, and infections. Tendon transfers may be considered at a later stage to increase an individual's functioning. Nerve transfer in patients with permanent upper limb deficits may be considered to restore or to improve ability to voluntarily activate a muscle. In a recent case report, a child who underwent multiple fascicle transfers from median and ulnar nerves to the musculocutaneous nerve, spinal accessory to suprascapular nerve, and medial cord to axillary nerve had excellent recovery of elbow flexion. However, shoulder abduction had improved only minimally after 22 months [32].

Potential Disease Complications

Potential disease complications resulting from spinal cord injury with its attendant sequelae are generally similar irrespective of the etiology. A common complication is pressure ulcer of the skin if pressure relief is not done regularly. Awareness of and monitoring for deep venous thrombosis and pulmonary embolism should be routine. There may be varying degrees of respiratory muscle weakness, and when it is severe, mechanical ventilation assistance may be required. Patients are at increased risk for pneumonia or sleep apnea from the illness, compounded by any sedating medications or respiration-depressing narcotics given.

Spasticity and joint contractures may result over time. Heterotopic ossification may surround a joint, further promoting contractures. Gastrointestinal complications may begin with an acute ileus followed by chronic constipation. Urinary tract infections are common because retained urine and instrumentation both increase the likelihood of infection. Autonomic dysreflexia may occur, especially for lesions above T6. Pain, a frequent complaint after spinal cord injury, is often attributed to either musculoskeletal sources or a "central" or neurogenic pain mechanism and in some studies affects more than 90% of individuals. Treatment initiated for this pain includes tricyclic antidepressants, anticonvulsants, analgesics, nonsteroidal anti-inflammatory drugs, or short courses of cyclooxygenase-2 inhibitors. Depression and anxiety may occur and usually respond to supportive counseling but may need antidepressants such as the selective serotonin reuptake inhibitor or the serotonin-norepinephrine reuptake inhibitor drugs.

Overuse syndromes can result because muscles and joints are commonly stressed in trying to maintain or to learn new functions. Shoulder pain is a prominent issue, and the problems of tendinitis, arthritis, rotator cuff tear, impingement, and contracture must be properly identified and managed or rehabilitated. Steroid and local anesthetic injections in the joint may sometimes be needed, but use of proper transfer techniques or specific adaptive equipment is often helpful. Pressure from prolonged resting on superficial nerves can also cause pain or weakness. There may be difficulty with reproduction and fertility problems in the younger patients, and sexuality issues and solutions should be addressed or referred to a specialist.

Potential Treatment Complications

Treatment complications may result from side effects of medications and equipment required to treat the disease

manifestations. Skin complications may result from ill-fitting devices or poorly applied dressings. Strictures or tracheal inflammation can result from tracheostomy tubes; if mechanical ventilation is required, failure of equipment can result in hypoxia or worse. Respiratory infections occur frequently with prolonged mechanical ventilation in high tetraplegia. High-dose steroids used to treat initial inflammation may cause gastritis, ulceration, or hemorrhage in the gastrointestinal tract. Deep venous thrombosis prophylaxis and anticoagulant treatment may result in or exacerbate bleeding tendencies. Catheterization may cause urinary tract infections or false passages in the urethra, making further catheterization difficult, with possible development of strictures. If bowel programs are not well managed, anal irritation may go on to skin maceration and breakdown around the sacral region.

CHAPTER 162

Traumatic Brain Injury

David T. Burke, MD, MA

Di Cui, MD

Synonyms

Head injury
Acquired brain injury
Concussion
Diffuse axonal injury

ICD-9 Codes

- 854.0** Intracranial injury of other and unspecified nature without mention of open intracranial wound
- 854.1** Intracranial injury of other and unspecified nature with open intracranial wound
- 907.0** Late effect of intracranial injury without mention of skull fracture

ICD-10 Codes

- S06.2X0-8** Diffuse traumatic brain injury (sixth digit will define the level of consciousness)
- S06.2X9** Diffuse traumatic brain injury with loss of consciousness of unspecified duration
- S06.300-389** Focal traumatic brain injury (fifth digit will define the location of injury, sixth digit will define the level of consciousness)
- S06.309** Unspecified focal traumatic brain injury with loss of consciousness of unspecified duration
- Add seventh character for episode of code;
S—late effect

Definition

Traumatic brain injury (TBI) is an insult to the brain from an external physical force and resulting in temporary or permanent impairment, functional disability, or psychosocial maladjustment. TBI occurs twice as frequently in males as in females. The incidence of TBI peaks among those 15 to 24 years old and again among those 75 years and older [1]. TBI usually is a consequence of motor vehicle accidents, falls, violence, and sports. Motor vehicle accidents and violence are more common in a younger population, and falls are more common in aging populations [2,3]. Recent trends have shown that TBI due to motor vehicle accidents is decreasing because of better traffic safety enforcement, whereas the percentage of TBI due to violence has increased, reported to be 7% to 10% [3]. These trends have consequences for the type of brain damage seen; contusion injury tends to be associated with falls, and diffuse injuries are more often seen in high-velocity traffic accidents [2].

In the United States, an average of 1.4 million TBIs occur each year, including 1.1 million emergency department visits, 235,000 hospitalizations, and 50,000 deaths [1,2,4,5]. The financial burden of TBI has been estimated at more than U.S. \$60 billion per year [2]. However, routinely reported U.S. national data underestimate the true burden of TBI for several reasons. First, they do not include persons treated for TBI in other settings, including outpatient settings and physicians' offices. Second, patients seen in military facilities both in the United States and abroad are not recorded. Finally, the number of those who receive medical care but for whom the TBI is not diagnosed or who sustain a TBI and do not seek care is not known [4,5].

The pathophysiologic process of brain injury is usually divided into primary injury, which is the injury to the brain that results at the time of the insult, and secondary injury, which can be thought of as the summation of the biochemical or physiologic damage that develops during a period of hours, days, weeks, and perhaps months after the primary injury. The primary injury is sustained from external forces as a result of direct impact, rapid velocity changes, penetrating injuries, or blast injuries. The resulting injuries include contusion, hematomas, and diffuse axonal injuries. These are often associated with superimposed hypoxic or ischemic injury, often as a result of systemic insult. In patients with mild TBI, there is often a disruption of the sodium

channels on axons, which can result in a transient disruption in function and, with it, an increased state of vulnerability to additional trauma [6]. Secondary insults include intracranial hemorrhage, swelling, hypoxia, brain shift, herniation, and numerous neurochemical and cellular events [2]. Although many of the mechanisms of secondary TBI have yet to be elucidated, it is thought that the processes include neurotransmitter release, free radical generation, calcium-mediated damage, inflammatory responses, and mitochondrial dysfunction [2,7].

Symptoms

Symptoms may vary according to the severity of the injury and the stage of recovery. The patient's history should include a detailed summary of the mechanism of injury, comorbid conditions, initial Glasgow Coma Scale score (Table 162.1), length of the coma (if any), and length of post-traumatic amnesia. Glasgow Coma Scale scores, however, can be obscured by confounders such as concurrent spinal cord injury, sedation, intubation, or other related injuries. Extracranial injuries (such as extremity fractures, thoracic or abdominal traumas), which have been reported to occur in about 35% of the cases, are associated with a higher incidence of secondary brain injuries [2,8].

Patients with severe injury and dramatically altered levels of arousal often can offer no subjective symptoms. After the acute phase of recovery, the clinician can expect symptoms to include seizures, contractures, spasticity, altered vision, vertigo or dizziness, and altered sense of smell. These may be the result of cranial nerve injuries or of central processing dysfunction. Symptoms of dysautonomia may still be seen at outpatient follow-up and may be characterized by increased body temperatures, tachycardia, tachypnea, increased posturing or tone, and profuse sweating [9]. Common late symptoms may include memory deficits, higher level executive dysfunction, headaches, difficulty with sleep-wake cycles, labile mood, depression, apathy, difficulty with attention, social disinhibition, sexual

dysfunction, anxiety, impulsivity, fatigue, and difficulties with fine and gross motor control [10].

Physical Examination

A thorough neurologic examination, including a neuropsychological evaluation, is important to assess the consequences of a brain injury. The neurologic examination evaluates mental status, cranial nerve function, vision, hearing, deep tendon reflexes, and abnormal reflexes. The examination should also evaluate muscle strength, tone, and coordination and assess gait or mobility in a wheelchair. It is important to create a thorough neuropsychological profile with the assistance of a neuropsychologist. This should be done to determine both physical abilities and the cognitive and emotional issues that will affect the patient's function. Cervical injury can be associated with TBI, especially in patients with a Glasgow Coma Scale score below 8 [11,12]. This must be recognized early to accurately assess injury severity and to determine treatment course.

Functional Limitations

Motor

Patients may have difficulty with mobility and self-care as a result of isolated motor weakness or coordination of either the upper or the lower extremities. Safe mobility may also be impeded by poor cognition, including deficits with planning and poor impulse control.

Behavior

Individuals often experience subtle or dramatic personality changes that alter relationships with others. These may include problems with the initiation of responses, verbal or physical aggression, altered emotional control, social disinhibition, depression, apathy, decreased sense of self-worth, and altered sexual function.

Social

Patients often are unable to return to work at their previous level of function. As a consequence, they may suffer significant economic strain and may have difficulty with their relationships, including their marriage. Studies have failed, however, to consistently show a significantly higher rate of divorce among those married at the time of injury [13]. Family members may be helpful in identifying issues of social isolation, depression, and anger.

Diagnostic Studies

Initial diagnostic studies can provide clues to the severity of the injury and will have prognostic implications. The IMPACT study suggests that in moderate to severe TBI, age, Glasgow Coma Scale motor scores, pupillary response, computed tomography characteristics, and the presence of subarachnoid hemorrhages are the most powerful independent prognostic factors for patient outcome. Other prognostic factors include hypotension, hypoxia, eye and verbal

Table 162.1 The Glasgow Coma Scale

components of the Glasgow Coma Scale, glucose level, platelet number, and hemoglobin concentration [14].

Imaging Studies

The initial computed tomography scan has been shown to be useful as an outcome predictor with use of the Traumatic Coma Data Bank classification or the Rotterdam computed tomography score [15]. Previous studies and guidelines have recommended computed tomography scans for all TBI patients with a Glasgow Coma Scale score of 14 and of 15 in the presence of risk factors, such as emesis, advanced age, duration of amnesia, injury mechanism, neurologic deficits, or anticoagulation (Table 162.2) [2,15–17]. More sophisticated testing has been introduced, including single-photon emission computed tomography, functional magnetic resonance imaging, and positron emission tomography, but for the most part, these are of little use in assessing the functional limitations caused by the injury. In patients with otherwise normal findings on neuroimaging, diffusion tensor imaging is emerging as a potential diagnostic tool for mild brain injury as it can detect white matter microstructure changes (Fig. 162.1) [18,19]. Despite the potential of new imaging techniques, TBI remains primarily a clinical diagnosis [20,21].

At the time of outpatient follow-up, it may be necessary to remind the patient and his or her caregivers of the extreme limitations of these studies and to focus on that patient’s functional abilities as the more important measure of the extent of the injury. In general, follow-up radiologic examinations are useful tools if the patient has excessively slow progress or has demonstrated a decline in function. These may be helpful in determining new or expanding lesions. Otherwise, these are generally of limited utility.

Table 162.2 Risk Factors for Intracranial Complications

Vomiting
Severe headaches
Age > 60 years
Coagulation disorder or anticoagulation
Trauma above the clavicle with clinical signs of skull fracture
Continued post-traumatic amnesia or retrograde amnesia longer than 30 minutes
Unclear mechanism of injury or intoxication with drug or alcohol

Biomarkers

The use of biomarkers to assess the magnitude of total brain injury and to localize brain injury is still in the investigatory phase. These markers may prove to be useful in patients with mild TBI with otherwise normal imaging findings as well as in patients whose injury severity cannot be accurately assessed because of confounders mentioned previously.

Biochemical markers of neuronal, glial, and axonal damage, such as neuron-specific enolase, S100B, and myelin basic protein, respectively, are readily detectable in biologic samples such as serum and cerebrospinal fluid and are being studied in patients with ischemic brain injury and TBI. These and others may soon be of use as an adjunct to neuroimaging in the early assessment of primary and evolving damage in traumatic and ischemic brain injury [22].

Functional Assessment Tools

One of the best diagnostic tools is the Glasgow Coma Scale, which is used for the initial evaluation of the severity of the patient’s injury (see Table 162.1). A review of this initial score will help in the determination of the extent of the injury and thus with prognostication. Later, as a review of function in the outpatient setting, progress can be measured by the Disability Rating Scale. Post-traumatic amnesia is important for prognostication as well and can be assessed by the Galveston Orientation and Amnesia Test. For the current level of functional recovery to be characterized, the Rancho Los Amigos Scale is helpful in the assessment of the patient’s awareness and interaction with the environment.

Neuropsychological Testing

This battery of tests, performed by a neuropsychologist, is the best means of determining the full spectrum of cognitive, affective, and emotional function of the individual. This may be completed before discharge from inpatient rehabilitation and should be repeated when a change in function needs to be documented. This testing may provide the clinician with critical information needed to understand the ability of the patient to progress toward more independence or responsibility at home or at work. This also may be a critical assessment tool for the documentation of the injury for insurance purposes.

FIGURE 162.1 Diffusion tensor imaging in traumatic brain injury: loss of white matter tract fibers after traumatic brain injury (right) compared with an age-matched control (left). (From Maas AI, Menon DK. Traumatic brain injury: rethinking ideas and approaches. *Lancet Neurol* 2012;11:12-13.)

Differential Diagnosis

Anoxic brain injury
Metabolic encephalopathy
Affective disorder
Depression
Whiplash-associated disorder

Treatment

Initial

The initial focus of treating a patient with a TBI is to reduce the magnitude of the secondary injury. If the initial injury is of sufficient severity, computed tomography or magnetic resonance imaging is needed to determine the need for surgical intervention. The scans are reviewed for signs of excessive bleeding, edema, and shifting of the brain. If these signs are absent, medical intervention addresses the possible secondary injury that may result. Although it is still unclear as to how long a window of opportunity exists to affect the extent of secondary injury, it is generally accepted that this opportunity is likely to occur within the time of the initial acute hospitalization [4]. For this reason, there is little opportunity to affect this process in the outpatient setting.

Initially, metabolic issues such as blood pressure, electrolytes, hydration and nutrition, infectious processes, sleep disturbances including sleep apnea, and medications need to be addressed. Any imbalance in these may inhibit the function of the surviving brain tissue. Hydration and nutrition should be well maintained. An individual with a brain injury may be unable or unwilling to take nutrients by mouth, and this may necessitate either intravenous or direct gastrointestinal feedings. This may be a significant issue well into the post-acute phase of recovery. A survey for possible infectious processes includes, at a minimum, the pulmonary and genitourinary systems. Even infections that a clinician may otherwise label subclinical can disrupt the function of a damaged brain. For this reason, such infections should be treated as potentially symptomatic.

Medications can have undesired negative effects among those with a brain injury. These need to be reviewed carefully to eliminate any that may interfere with cognitive function. The list is long, but the most common offenders include antiseizure medications, antihypertensive medications, antispasticity medications, neuroleptics, sedatives, hypnotics, and gastrointestinal medications. Some of these may be unnecessary, whereas others may have less disruptive alternatives.

In addition to neuropsychological testing of the cognitive performance of the patient, psychological services are important in the assessment and treatment of affective disorders, which may include depression, apathy, and post-traumatic stress disorder. It is important to consider psychology services as being useful for the family and support system because the stress on these individuals may be tremendous. Psychologists and behavior specialists may be helpful for the intervention into behavior issues.

Arousal

Arousal will fluctuate throughout the day for a person with brain injury. Fatigue may become a long-standing problem.

Frequent rests and naps may be needed, even at more than 1 year after injury. Pharmacologic interventions may be initiated for hypoarousal and excessive fatigue. These include amantadine, bromocriptine, carbidopa/levodopa, methylphenidate, modafinil, atomoxetine, amphetamine, nortriptyline, and protriptyline [23]. In a double-blind clinical trial, amantadine has been shown to accelerate the pace of functional recovery in patients with severe brain injury [24].

Attention

Neuropharmacologic agents for attention are similar to those used for arousal. These include neurostimulants, such as methylphenidate, modafinil, and atomoxetine, and dopaminergic agents, including amantadine, bromocriptine, and carbidopa/levodopa. Antidepressants include a long list of mixed as well as selective serotonin reuptake inhibitors; these will be especially useful if there is an element of depression interfering with cognition.

Agitation

Because agitation is a common and often troubling issue among those recovering from a TBI, a careful selection of pharmacologic agents is important to prevent injury, to allow focus on rehabilitation, and to reduce the stress on caregivers. In general, the agents that are preferred help control behavior while producing the least reduction in cognition. Because benzodiazepines are thought to have the potential of interfering with the recovery of the injured brain, these are often not recommended in the early stages of recovery. Other medications are therefore used as first-line agents. As an anxiolytic, buspirone seems preferable. A clinician may use antiseizure medications as a mood stabilizer (e.g., divalproex sodium, carbamazepine), newer antipsychotic medications (e.g., risperidone, quetiapine), beta blockers (e.g., propranolol), and antidepressants for anxious or agitated patients. Because poor attention to the environment may result in behavioral agitation, medications such as amantadine and methylphenidate should also be considered useful agents.

Memory

Because memory requires both arousal and attention, the medications previously discussed may produce improvements in the ability to learn. In addition, there have been limited reports of positive results through the use of donepezil, memantine, and other similar drugs. Memory can also be enhanced through the use of compensatory strategies and services. Speech pathologists can be useful for the introduction of and training in some of these strategies. There are portable electronic devices that can be preprogrammed with important information, and these memory aids can be frequently updated for individuals whose TBI may interfere with the ability to program the electronic memory aids.

Seizures

There is a reasonable body of literature to suggest that the use of antiseizure medications is not warranted if no seizure occurs within the first week after the brain injury. If the patient experiences a seizure after 1 week, the use of anticonvulsant agents may be needed for an extended time until

the patient is seizure free for a period of 2 to 5 years; the patient is then to be reevaluated and managed per standard guidelines for patients with new-onset seizures [25,26]. Recommended agents depend on seizure type and usually include carbamazepine, valproic acid, and gabapentin.

Spasticity

Spasticity is a common problem among patients with brain injury (see Chapter 153). Patients may also have hyperactive muscle stretch reflexes and clonus. If these problems are not addressed, early contracture of joints may result. The modified Ashworth scale can be used to measure the degree of spasticity. As a first step of intervention, the clinician should look to reduce noxious stimuli, including anything that may produce pain. Infectious issues, positioning, and seating should be addressed as potential offenders. Stretching should be initiated and may necessitate serial casting and splinting. If medications are needed, these may include tizanidine, clonidine, dantrolene, diazepam, and baclofen. All of these agents have potential side effects and should be used judiciously. Dantrolene is unique in its lack of central effect but often results in acute liver dysfunction.

Rehabilitation

The rehabilitation of patients with brain injury begins during the acute stage of treatment when the risks of secondary brain injury are the greatest. After the acute phase, it is important that the clinician review the potential pharmacologic management and combine this with an interdisciplinary group of therapies, depending on the specific deficits of the patient. Studies have suggested that early admission to a dedicated inpatient brain rehabilitation unit is associated with reduced overall cost as well as improved outcome [27].

Physical Therapy

Physical therapy is important for the restoration of range of motion of the lower extremities and, if needed, through the use of serial casting. This may be aided by neurolysis or blocks at the neuromuscular junction. Later, issues of wheelchair preparation and propulsion may be important for those with sufficient impairment of mobility. Ambulation training with the appropriate assistive device should be frequently reviewed as the patient progresses with ambulation. Safety must always be considered because the patient with TBI may be endangered by impulsivity or poor planning and judgment.

Occupational Therapy

Occupational therapy addresses the preservation of joints when a lack of strength or an excess in tone or spasticity threatens a joint. As strength and ataxia are often issues in the first year, these should be addressed individually. The issues of self-care, including daily activities such as dressing, bathing, and grooming, must be addressed and emphasize the need for a planning strategy for the patient. Cooking and driving evaluations may be needed to advise the patient before his or her return to the home.

Speech Therapy

Early in the care of the patient, the ability to swallow safely needs to be evaluated. In addition, the speech pathologist,

ideally working with the neuropsychologist, can identify focal cognitive needs of the patient and addresses these over a length of time. These often involve memory strategies, such as mnemonic training, and pragmatics, which focus on the contextual and social aspects of communication skills. Published cognitive rehabilitation studies have generally supported the efficacy of interventions that target memory [28–31]. These memory strategies, as a part of a comprehensive cognitive rehabilitation program, may enhance a partial restoration of focal activities in regions of the brain associated with memory, such as the hippocampus [32].

Vocational Rehabilitation

Many patients will have difficulty in returning to their previous level of employment. Vocational rehabilitation counselors can evaluate a patient's skills and determine the need for training.

Procedures

For spasticity, local injections may be preferable to oral medications. These may include nerve root blocks, nerve blocks, motor unit blocks (all with phenol), and neuromuscular junction blocks (with botulinum toxin). When spasticity is severe and not responsive to these interventions, an intrathecal pump may be considered for continuous infusion of baclofen into the cerebrospinal fluid (refer to Chapter 153).

Surgery

Patients with new-onset hydrocephalus may need a shunt placed to reduce the pressure load at the brain. If medications and other measures fail to control spasticity and contractures result, surgery may be an option. If joint contractures occur, a surgical release may be indicated.

Potential Disease Complications

Seizures can result from a TBI. The risk is highest early after the injury but persists for years. Soon after the injury, patients are at risk for aspiration pneumonia and, if their swallowing is impaired, for malnutrition and dehydration. Sleep apnea is a frequent early issue. If not treated, it may exacerbate the symptoms of the TBI. Continuous positive airway pressure may be an effective treatment. As with all trauma patients, there is a risk for deep venous thrombosis (see Chapter 127). This must be treated with prophylactic heparin or, if hemorrhage is a risk, with pneumatic compression devices or an inferior vena cava filter.

Potential Treatment Complications

Medications that are used to treat attention and arousal may lead to excess arousal and agitation. This may also be manifested as somatic complaints or delirium. Medications for agitation and seizures may slow the patient's recovery over time and may reduce the patient's function while the medications are taken. Refer to [Table 162.3](#).

Table 162.3 Medications Frequently Used in Traumatic Brain Injury

Symptoms	Medication	Initial Dose	End Dose
Arousal	Amantadine	50 mg, 8 AM and 2 PM	100 mg, 8 AM and 2 PM
	Bromocriptine*	1.25 mg, 8 AM and 2 PM	5.0 mg, 8 AM and 2 PM
	Carbidopa/levodopa*	10 mg/100 mg tid	25 mg/100 mg tid
	Methylphenidate	2.5 mg, AM and 2 PM	20 mg, AM and 2 PM
	Modafinil	100 mg qd	100 mg, 8 AM and 2 PM
	Dextroamphetamine (Dexedrine)	5 mg qd	30 mg, AM and 2 PM
Attention	Methylphenidate	2.5 mg, AM and 2 PM	20 mg, AM and 2 PM
	Adderall	5 mg bid	20 mg bid
	Modafinil	100 mg, AM	100 mg, AM and PM
	Amantadine	100 mg, AM	150 mg, AM and 2 PM
	Bromocriptine*	1.25 mg, AM	50 mg, 8 AM and 2 PM
	Carbidopa/levodopa*	10 mg/100 mg tid	25 mg/100 mg tid
	Sertraline (Zoloft)	50 mg qd	200 mg qd
	Citalopram (Celexa)	20 mg qd	40 mg qd
	Donepezil (Aricept)	2.5 mg qd	5 mg bid
	Memantine (Namenda)	5 mg qd	10 mg qd
	Atomoxetine (Strattera)	20 mg qd	60 mg qd
	Buspirone	7.5 mg bid	30 mg bid
Agitation	Carbamazepine	200 mg bid	600 mg bid
	Risperidone	1 mg bid	6 mg/day
	Morphine	10 mg q4h	10 mg q4h
	Propranolol	10 mg qd	Limited by heart rate and blood pressure
	Quetiapine (Seroquel)	25 mg qd	800 mg qd

*Limited by hypotension.

 Levator scapulae muscles, 91–92, 92*f*
 Levetiracetam, for brachial plexopathy, 760
 Levodopa, for Parkinson disease, 692–693, 748, 748*t*, 750
 Levodopa-induced dyskinesias, in Parkinson disease, 750
 Lhermitte sign, 4, 26, 482
 in cervical spinal stenosis, 36, 36*f*
 in multiple sclerosis, 696
 rheumatoid arthritis of, 815
 Libido, loss of, in stroke, 864
 Lidocaine
 for adhesive capsulitis, 55
 for chemotherapy-induced peripheral neuropathy, 483
 for coccydynia, 493
 for complex regional pain syndrome, 499
 for post-mastectomy pain syndrome, 551
 for postherpetic neuralgia, 545–546, 547
 for trigeminal neuralgia, 592, 592*t*
 for wrist osteoarthritis, 198
 for wrist rheumatoid arthritis, 208
 Lidoderm
 for intercostal neuralgia, 517
 for thoracic sprain or strain, 223

Lifestyle modification
 for cluster headache, 512
 for migraine, 511–512
 for tension-type headache, 512
 LifeViz system, for pressure ulcers, 794*f*
 Lift-off test, 67, 67*f*, 81
 Ligamentous injuries, gradations of, 426, 427*f*
 Ligamentous laxity, 431
 Linear array ultrasound-voiding
 cystourethrogram, 723*f*
 Lipedema, in lymphedema, 677
 Liposuction, for lymphedema, 679
 Little Leaguer's elbow, 116
 Load and shift maneuver, 68
 Local anesthetic injection, 433
 Long thoracic nerve, 92*f*
 injury in, 90, 93*f*
 Loose body, in ankle arthritis, 423
 Lordosis, and neural tube defects, 713
 Low back strain/sprain, 244–248, 245*t*, 246*t*
 Low-molecular-weight heparin (LMWH), 656, 657*t*
 Lower motor neuron bowel syndrome, 727
 Lubricated single-digit examination, 537
 Ludington test, 63, 63*f*
 Lumbar degenerative disease, 225–232, 226*f*, 227*t*, 228*f*, 229*t*, 230*t*
 Lumbar degenerative scoliosis, 824, 826
 Lumbar facet arthropathy, 233–236, 234*f*
 Lumbar plexus, 762, 763*f*
 Lumbar puncture, in transverse myelitis, 888
 Lumbar radiculitis, 237
 Lumbar radiculopathy, 237–243, 238*t*, 240*f*
 Lumbar spine
 muscle stabilization program for, 228–230
 normal anatomic structures of, 258*f*
 spondylolisthesis of, 249–256, 250*f*, 250*t*, 252*f*, 253*f*
 spondylolysis of, 249–256, 250*f*, 251*f*, 252*f*, 253*f*
 stenosis of, 257–263, 258*t*, 260*t*
 Lumbar strain/sprain, 244
 Lumbar sympathetic block, in complex regional pain syndrome, 499
 Lumbosacral myotomes, muscle groups for, 859*t*
 Lumbosacral orthosis, in thoracic compression fracture, 212–213, 214*f*
 Lumbosacral plexopathy, 762–768
 Lumbosacral spinal segments, sensory points for, 859*t*
 Lumbosacral stabilization program, 241
 Lunate
 Kienböck disease of, 169, 170*f*, 170*t*, 171*f*
 revascularization of, 172
 Lung disease, pulmonary rehabilitation for
 patients with, 800–806
 symptoms of, 800, 801*f*
 Lung volume recruitment, 808–809
 Lung volume reduction surgery, 805
 Luschka, joints of, 12–13, 13*f*
 Lymph node dissection, lymphedema and, 679
 Lymphadenopathy, metastatic, 759
 Lymphangiosarcoma, lymphedema and, 679
 Lymphatic examination, in post-mastectomy pain syndrome, 549–550
 Lymphatic system, 676
 manual drainage of, 678–679
 Lymphaticovenous anastomosis, 679
 Lymphedema, 676–680, 677*f*, 677*t*, 678*f*
 malignant, 678

M
 Macrotrauma, temporomandibular joint dysfunction and, 567
 Magnesium, intravenous, for complex regional pain syndrome, 498

- Magnetic resonance arthrography
 in adhesive capsulitis of hip, 273, 273f
 in chronic ankle instability, 436, 436f

Psychological interventions, in chronic pain syndrome, 487

Psychological treatment, in Tietze syndrome, 586

Psychopharmacologic treatment, in Tietze syndrome, 586

Psychosocial adaptation, 852–853

Psychostimulants, in postconcussion symptoms, 787

Pubalgia, 304–307

- definition of, 304
- diagnostic studies for, 306
- functional limitations with, 306
- initial treatment of, 306
- physical examination in, 304–306
- potential disease complications of, 306–307
- potential treatment complications of, 307
- procedures for, 306
- rehabilitation for, 306
- surgery for, 306
- symptoms of, 304

Puborectalis syndrome, in coccydynia, 491

Pudendal nerves, 715

Pulled upper back, 221

Pulmonary embolism

- prophylaxis for, 413
- thoracic spinal cord injury and, 853–854

Pulmonary rehabilitation, 802*t*, 807–812, 808*f*

- diagnostic studies for, 807–808
- disease complications in, 810–811
- functional limitations in, 807
- in lung disease, 800–806
- for motor neuron disease, 687–688
- physical examination in, 807
- in post-thoracotomy pain syndrome, 553
- pulmonary hygiene options in, 804*t*

Pulmonary rehabilitation (*Continued*)

- symptoms in, 807
- treatment complications in, 811
- treatment in, 808–810
- types of exercise in, 803*t*

Pulpitis, chronic, 590*t*

Pulsed radiofrequency, in coccydynia, 493

Pump bump, 439

Q

Q angle, 385, 385*f*

Quadriceps contusion, 308–311

- definition of, 308
- diagnostic studies for, 309
- functional limitations with, 309
- initial treatment of, 309
- physical examination in, 308–309
- potential disease complications of, 310
- potential treatment complications of, 310
- procedures for, 310
- rehabilitation for, 309–310
- surgery for, 310
- symptoms of, 308

Quadriceps tendinitis, 399–400

Quadriceps tendinopathy, 399–400

Quadriceps tendon

- definition of, 399
- rupture, 308–309

Quadriceps testings, 281–282

R

Radial deviation, wrist rheumatoid arthritis, 203–204

Radial nerve, 129, 130*f*, 131*f*

- decompression of, 132

Radial neuropathy, 129–132, 130*f*, 131*f*, 131*t*, 132*f*

Radial palsy splint, 132*f*

Radial pulse, in thoracic outlet syndrome, 577

Radial shortening, in Kienböck disease, 172

Radiation fibrosis syndrome, 555–560, 556*f*, 557*f*

Radiation fields, used to treat Hodgkin lymphoma, 556*f*

Radiation therapy

- in cancer-related fatigue, 631
- in heterotopic ossification, 673–674

Radiculopathy

- cervical, 13, 22–30
- lumbar, 237–243, 238*t*, 240*f*
- thoracic, 217–220

Radiculoplexus neuropathy, lumbosacral, 765

Radiofrequency neurotomy, in sacroiliac joint dysfunction, 268

Radiofrequency (RF) ablation, 592

Radiographic grading scales, in stress fracture, of lower limb, 408

Radiography

- in acromioclavicular injuries, 48, 49*f*
- in adhesive capsulitis, 54
- in ankle arthritis, 424, 424*f*
- in ankylosing spondylitis, 611
- in anterior cruciate ligament tear, 325
- in biceps tendinopathy, 59
- in biceps tendon rupture, 63–64
- in brachial plexopathy, 758
- in bunions, 432
- in carpal tunnel syndrome, 175*f*, 176
- in cerebral palsy, 639
- in cervical degenerative disease, 14
- in cervical dystonia, 18–19
- in cervical facet arthropathy, 9*f*
- in cervical radiculopathy, 26–27
- in cervical spinal stenosis, 37*f*

Radiography (*Continued*)

- in cervical spondylotic myelopathy, 4–5
- in cervical strain/sprain, 32, 32*f*
- in chronic ankle instability, 436
- in chronic obstructive pulmonary disease, 801
- in coccydynia, 491*f*, 492
- in collateral ligament sprain, 341
- in complex regional pain syndrome (CRPS), 497, 498
- in costosternal syndrome, 502
- in extensor tendon injuries, 146
- in foot and ankle bursitis, 441, 441*t*
- in glenohumeral instability, 68–69
- in glenohumeral osteoarthritis, 98*f*
- in hallux rigidus, 445–446, 446*f*, 447*f*
- in hamstring strain, 352
- in hand osteoarthritis, 161
- in heterotopic ossification, 671*f*, 672
- in hip adhesive capsulitis, 272
- in hip disease, 314, 315*f*
- in hip labral tears, 293
- in hip osteoarthritis, 287, 287*f*
- in jumper's knee, 381
- in Kienböck disease, 169–170, 170*f*
- in knee bursitis, 370
- in knee osteoarthritis, 363, 363*f*
- in lumbar facet arthropathy, 234, 234*f*
- in lumbar radiculopathy, 239
- in lumbar spinal stenosis, 260*t*
- in lumbosacral spinal cord injury, 861
- in mallet toe, 453
- in meniscal injuries, 376–377
- in Morton neuroma, 460
- in occipital neuralgia, 528–529, 530*f*
- in olecranon bursitis, 126, 126*f*
- in osteoarthritis, 735
- pelvis, in pubalgia, 306
- in polytrauma, 771
- in post-thoracotomy pain syndrome, 553
- in postconcussion symptoms, 785
- in posterior tibial tendon dysfunction, 469, 469*f*
- in postpoliomyelitis syndrome, 778
- in quadriceps contusion, 309
- in radiation fibrosis syndrome, 557
- in repetitive strain injuries, 564
- in rheumatoid arthritis, 108*t*, 109*f*
- in rotator cuff tear, 86–87
- in rotator cuff tendinopathy, 81
- in scapular winging, 94
- in scoliosis and kyphosis, 823
- in shin splints, 402
- in shoulder arthritis, 98
- in spondylolysis, 251–252, 251*f*
- in temporomandibular joint dysfunction, 568–569
- in thoracic compression fracture, 212, 213*f*
- in thoracic outlet syndrome, 578
- in thoracic radiculopathy, 218
- in tibial neuropathy, 473
- in Tietze syndrome, 583
- in total knee replacement, 413
- in ulnar collateral ligament sprain, 185
- in ulnar neuropathy, 134, 191
- in wrist osteoarthritis, 195*f*, 197, 200*f*
- in wrist rheumatoid arthritis, 205, 206*f*, 207*f*

Radionuclide bone scanning, in shin splints, 402

Raloxifene, in osteoporosis, 743

Ramsectomy, in cervical dystonia, 20

Ramsay Hunt syndrome, 545

Rancho Los Amigos Scale, 894

Range of motion

- ankle
- in arthritis, 423
- in sprain, 429

- Range of motion (*Continued*)
 cervical spine
 in radiculopathy, 24
 in strain/sprain, 31
 in chronic ankle instability, 437
 of elbow, 108
 in femoral neuropathy, 283
 in hamstring strain, 353
 hip, 304–306
 adductor strain, 279
 labral tears, 294
 in lower limb amputation, 605
 osteoarthritis, 286
 joint
 in cerebral palsy, 638
 contractures, 649*t*
 knee
 in lower limb amputation, 605
 in meniscal injuries, 378
 in quadriceps contusion, 308–309
 in mallet toe, 452
 in post-mastectomy pain syndrome, 550
 in post-thoracotomy pain syndrome, 554
 shoulder
 in acromioclavicular injuries, 47
 in adhesive capsulitis, 53–54
 in arthritis, 98
 in biceps tendinopathy, 58–59
 in glenohumeral instability, 67
 in rotator cuff tear, 87–88
 in rotator cuff tendinopathy, 82–83
 in scoliosis and kyphosis, 823
 in spasticity, 829–830
 in thoracic radiculopathy, 218
 in thoracic sprain or strain, 222
 in total knee replacement, 412*t*, 416
 in trapezius strain, 43
 wrist, in wrist osteoarthritis, 195, 197
 Rasagiline, in Parkinson disease, 748–749, 748*t*
 Rash, in rheumatoid arthritis, 813
 Rashes, in systemic lupus erythematosus (SLE), 878
 Raynaud phenomenon, 879
 Recalcification, in acromioclavicular injuries, 52
 Recreational therapist, 488
 Rectum
 bleeding from, 858
 examination of, 859
 Rectus abdominis, 305*f*
 Reflex myoclonus, 691
 Reflex sympathetic dystrophy, 495–496
 in stroke, 865
 Reflex(es)
 bulbocavernosus, 728
 in cerebral palsy, 638
 in cervical radiculopathy, 24, 25*f*, 25*t*
 loss, in lumbar radiculopathy, 238*t*
 micturition, 715
 in multiple sclerosis, 698
 in neurogenic bladder, 717–718
 in thoracic sprain or strain, 222
 Refrigerant spray, 586
 Regional blocks, in brachial plexopathy, 759
 Rehabilitation
 cardiac, 622–627, 624*t*, 625*t*, 626*t*
 in pubalgia, 306
 Relative stenosis, 257–258
 Relaxation, in cardiac rehabilitation, 624
 Relocation maneuver, 67–68
 Relocation test, in rotator cuff tendinopathy, 81, 82*f*
 Renal ultrasonography, 881–882
 Repetitive strain injuries, 561–566, 562*f*, 563*f*
 trapezius, 43
 Residual limb pain, 605
 Resisted abduction (REAB) test, in sacroiliac joint dysfunction, 267
 Respiratory failure
 in motor neuron disease, 682, 687
 in multiple sclerosis, 701
 Respiratory muscle dysfunction, 807–808
 Respiratory problems, in postpoliomyelitis syndrome, 777, 778, 779
 Restrictive lung disease, in neural tube defects, 710
 Retinacular cyst, 155, 156*f*, 157
 Retroachilles bursitis, 440*t*, 441, 441*t*, 442*t*
 Retrocalcaneal bursitis, 440*t*, 441, 441*t*, 442*t*
 Retrocollis, 18
 Retrolisthesis, 250
 Retroperitoneal fibrosis, 297*t*
 Retroperitoneal tumor, 297*t*
 Revascularization procedure, in Kienböck disease, 172
 Reverse pivot shift test, 395, 396*f*
 Reverse straight-leg raise, in low back strain/sprain, 246*t*
 Rheumatoid arthritis, 813–819, 814*t*, 815*t*
 of hands, 165–168, 166*f*, 814, 816*f*
 Larsen radiographic staging of, 206*t*
 nodules, 814
 radiographic classification of, 108*t*
 radiography of, 109*f*
 side effects of medications used in patients with, 818*t*
 of wrist, 203–210, 814, 816*f*
 Rheumatoid factor, 815
 Rhizotomy
 in cerebral palsy, 640
 in occipital neuralgia, 529
 Ribs
 cervical, 575
 first, 575–576, 579, 579*f*
 motion of, in thoracic sprain or strain, 222
 Rigid dressing, in lower limb amputation, 607, 607*f*, 607*t*
 Riluzole, for amyotrophic lateral sclerosis, 685
 Risedronate, in osteoporosis, 743
 Rituximab, for hand rheumatoid arthritis, 166
 Rocker-bottom shoes, in stress fractures, of lower limb, 409
 Rome III criteria, 535
 Roos test
 in cervical radiculopathy, 26
 in thoracic outlet syndrome, 577
 Root tension signs, in low back strain/sprain, 246*t*
 Ropinirole, in Parkinson disease, 748, 748*t*
 Rotator cuff
 functions of, 85
 impingement test of, 67–68, 68*f*, 69*f*
 muscles of, 86*f*
 tear of, 85–89, 86*f*, 872*t*
 tendinopathy of, 80–84. *see also*
 Tendinopathy
 Running program, in plantar fasciitis, 465
S
 Sacral nerve stimulation, in neurogenic bladder, 723
 Sacral plexus, 762, 764*f*
 Sacral sulcus
 pressure at, in low back strain/sprain, 246*t*
 pressure over, 267
 Sacroiliac joint, 264–265, 265*f*
 compression maneuver for, in low back strain/sprain, 246*t*
 dysfunction of, 264–269, 266*f*, 267*f*
 Sacrum, fractures of, 763
 Saline injections, in adhesive capsulitis, 57
 Saturday night palsy, 129–130
 Sauvé-Kapandji procedure, 209
 Scalene muscle
 activation of, 579, 579*f*
 botulinum chemodenervation of, 580
 Scalenotomy, in thoracic outlet syndrome, 580
 Scaphoid nonunion advanced collapse (SNAC), 195, 195*f*, 197*f*
 pattern of arthritic progression in, 195*f*
 Scaphoid shift test of Watson, 196–197
 Scapholunate advanced collapse (SLAC), 195, 196*f*
 Scapula, stabilization of, in rotator cuff tear, 87
 Scapular winging, 90–96, 91*t*, 93*f*
 Scar, in post-thoracotomy pain, 553–554
 Scarf test, 59
 Scarring
 alopecia, 880
 in burns, 618, 619
 Scheuermann kyphosis, 229*t*
 Schober test, 609–610
 Schroth method, 825
 Sciatic nerve, 300, 301*f*
 Sciatic neuropathy, 300
 Scoliosis, 229*t*, 820–827, 821*f*, 822*t*
 and neural tube defects, 713
 “Second impact syndrome,” 788
 Sedating agents, in postconcussion symptoms, 787
 Seizures
 cerebral palsy and, 636
 in stroke, 868
 in traumatic brain injury, 895–896
 Selective estrogen receptor modulators, for osteoporosis, 743
 Selective nerve root block, in cervical radiculopathy, 28
 Selective serotonin reuptake inhibitors (SSRIs), for motor neuron disease, 686
 Selegiline, in Parkinson disease, 748–749, 748*t*
 Selenium, for lymphedema, 678
 Self-reported impairments in Persons with late effects of Polio (SIPP) scale, 779–780
 Semantic paraphasia, 834–835
 Semimembranosus bursitis, 370
 Semmes-Weinstein monofilaments, 197
 Senile tremor, 691–692
 Sensation
 in diabetic foot, 661
 in thoracic sprain or strain, 222
 Sensory deficits
 in cervical spondylotic myelopathy, 4
 in multiple sclerosis, 698–699
 in peroneal neuropathy, 390, 390*f*, 391*f*
 Sensory discrimination training, in phantom limb pain, 542
 Sensory examination, in lumbosacral spinal cord injury, 859, 859*t*
 Sensory function
 in cervical degenerative disease, 13–14, 14*t*
 in cervical radiculopathy, 24, 25*f*
 in cervical spinal cord injury, 839
 in lateral femoral cutaneous neuropathy, 296
 in ulnar neuropathy, 191
 Sensory loss, in lumbar radiculopathy, 237, 238*t*
 Sensory nerves, in chemotherapy-induced peripheral neuropathy, 482
 Sensory system, in complex regional pain syndrome, 496
 Sensory testing, in post-mastectomy pain syndrome, 549–550
 Sensory tricks, in dystonia, 694
 Sentinel node biopsy, in lymphedema, 678
 Sepsis, olecranon bursitis and, 128
 Septic arthritis, acute, 97
